PyOxidizer is a utility that aims to solve the problem of how to distribute Python applications. See *Overview* for more or dive into *Getting Started* to learn how to start using PyOxidizer.

The official home of the PyOxidizer project is https://github.com/indygreg/PyOxidizer. Official documentation lives at Read The Docs (unreleased/latest commit, last release).

The pyoxidizer-users mailing list is a forum for users to discuss all things PyOxidizer.

If you want to financially contribute to PyOxidizer, do so on Patreon or via PayPal.

The creator and maintainer of PyOxidizer is Gregory Szorc.

# CHAPTER 1

### Overview

From a very high level, PyOxidizer is a tool for packaging and distributing Python applications. The over-arching goal of PyOxidizer is to make this (often complex) problem space simple so application maintainers can focus on building quality applications instead of toiling with build systems and packaging tools.

On a lower, more technical level, PyOxidizer has a command line tool - pyOxidizer - that is capable of building binaries (executables or libraries) that embed a fully-functional Python interpreter plus Python extensions and modules *in a single binary*. Binaries produced with PyOxidizer are highly portable and can work on nearly every system without any special requirements like containers, FUSE filesystems, or even temporary directory access. On Linux, PyOxidizer can produce executables that are fully statically linked and don't even support dynamic loading.

The Oxidizer part of the name comes from Rust: binaries built with PyOxidizer are compiled from Rust and Rust code is responsible for managing the embedded Python interpreter and all its operations. But the existence of Rust should be invisible to many users, much like the fact that CPython (the official Python distribution available from www.python.org) is implemented in C. Rust is simply a tool to achieve an end goal (albeit a rather effective and powerful tool).

# 1.1 Benefits of PyOxidizer

You may be wondering why you should use or care about PyOxidizer. Great question!

Python application distribution is generally considered an unsolved problem. At PyCon 2019, Russel Keith-Magee identified code distribution as a potential *black swan* for Python during a keynote talk. In their words, *Python hasn't ever had a consistent story for how I give my code to someone else, especially if that someone else isn't a developer and just wants to use my application.* The over-arching goal of PyOxidizer is to solve this problem. If we're successful, we help Python become a more attractive option in more domains and eliminate this potential *black swan* that is an existential threat for Python's longevity.

On a less existential level, there are several benefits to PyOxidizer.

### 1.1.1 Ease of Application Installation

Installing Python applications can be hard, especially if you aren't a developer.

Applications produced with PyOxidizer are self-contained - as small as a single file executable. From the perspective of the end-user, they get an executable containing an application that *just works*. There's no need to install a Python distribution on their system. There's no need to muck with installing Python packages. There's no need to configure a container runtime like Docker. There's just an executable containing an embedded Python interpreter and associated Python application code and running that executable *just works*. From the perspective of the end-user, your application is just another platform native executable.

### 1.1.2 Ease of Packaging and Distribution

Python application developers can spend a large amount of time managing how their applications are packaged and distributed. There's no universal standard for distributing Python applications. Instead, there's a hodgepodge of random tools, typically different tools per operating system.

Python application developers typically need to *solve* the packaging and distribution problem N times. This is thankless work and sucks valuable time away from what could otherwise be spent improving the application itself. Furthermore, each distinct Python application tends to solve this problem redundantly.

Again, the over-arching goal of PyOxidizer is to provide a comprehensive solution to the Python application packaging and distribution problem space. We want to make it as turn-key as possible for application maintainers to make their applications usable by novice computer users. If we're successful, Python developers can spend less time solving packaging and distribution problems and more time improving Python applications themselves. That's good for the Python ecosystem.

# **1.2 Components**

The most visible component of PyOxidizer is the pyoxidizer command line tool. This tool contains functionality for creating new projects using PyOxidizer, adding PyOxidizer to existing projects, producing binaries containing a Python interpreter, and various related functionality.

The pyoxidizer executable is written in Rust. Behind that tool is a pile of Rust code performing all the functionality exposed by the tool. That code is conveniently also made available as a library, so anyone wanting to integrate PyOxidizer's core functionality without using our pyoxidizer tool is able to do so.

The pyoxidizer crate and command line tool are effectively glorified build tools: they simply help with various project management, build, and packaging.

The run-time component of PyOxidizer is completely separate from the build-time component. The run-time component of PyOxidizer consists of a Rust crate named pyembed. The role of the pyembed crate is to manage an embedded Python interpreter. This crate contains all the code needed to interact with the CPython APIs to create and run a Python interpreter. pyembed also contains the special functionality required to import Python modules from memory using zero-copy.

# 1.3 How It Works

The pyoxidizer tool is used to create a new project or add PyOxidizer to an existing (Rust) project. This entails:

- Generating a boilerplate Rust source file to call into the pyembed crate to run a Python interpreter.
- Generating a working pyoxidizer.bzl configuration file.
- Telling the project's Rust build system about PyOxidizer.

When that project's pyembed crate is built by Rust's build system, it calls out to PyOxidizer to process the active PyOxidizer configuration file. PyOxidizer will obtain a specially-built Python distribution that is optimized for

embedding. It will then use this distribution to finish packaging itself and any other Python dependencies indicated in the configuration file. For example, you can process a pip requirements file at build time to include additional Python packages in the produced binary.

At the end of this sausage grinder, PyOxidizer emits an archive library containing Python (which can be linked into another library or executable) and *resource files* containing Python data (such as Python module sources and bytecode). Most importantly, PyOxidizer tells Rust's build system how to integrate these components into the binary it is building.

From here, Rust's build system combines the standard Rust bits with the files produced by PyOxidizer and turns everything into a binary, typically an executable.

At run time, an instance of the OxidizedPythonInterpreterConfig struct from the pyembed crate is created to define how an embedded Python interpreter should behave. (One of the build-time actions performed by PyOxidizer is to convert the Starlark configuration file into a default instance of this struct.) This struct is used to instantiate a Python interpreter.

The pyembed crate implements a Python *extension module* which provides custom module importing functionality. Light magic is used to coerce the Python interpreter to load this module very early during initialization. This allows the module to service Python import requests. The custom module importer installed by pyembed supports retrieving data from a read-only data structure embedded in the executable itself. Essentially, the Python import request calls into some Rust code provided by pyembed and Rust returns a void \* to memory containing data (module source code, bytecode, etc) that was generated at build time by PyOxidizer and later embedded into the binary by Rust's build system.

Once the embedded Python interpreter is initialized, the application works just like any other Python application! The main differences are that modules are (probably) getting imported from memory and that Rust - not the Python distribution's python executable logic - is driving execution of Python.

Read on to *Getting Started* to learn how to use PyOxidizer.

# CHAPTER 2

# **Getting Started**

## 2.1 Python Requirements

PyOxidizer currently targets Python 3.8 or 3.9. Your Python application will need to already be compatible with 1 of these versions for it to work with PyOxidizer. See *Why is Python 3.8 Required?* for more on the minimum Python requirement.

# 2.2 Operating System Requirements

PyOxidizer itself is a Rust program and should theoretically be installable on any environment that Rust supports.

However, PyOxidizer needs to run Python interpreters on the machine performing build/packaging actions and the built binary needs to run a Python interpreter for the target architecture and operating system. These Python interpreters need to be built/packaged in a specific way so PyOxidizer can interact with them.

See *Available Python Distributions* for the full list of available Python distributions. The supported operating systems and architectures are:

- Linux x86\_64 (glibc 2.19 or musl linked)
- Windows 7+ x86 and x86\_64
- macOS 10.9+ Intel x86\_64

# 2.3 Installing

### 2.3.1 Installing Rust

PyOxidizer is a Rust application and requires Rust (1.40 or newer) to be installed in order to build PyOxidizer itself as well as Python application binaries.

You can verify your installed version of Rust by running:

```
$ rustc --version
rustc 1.46.0 (04488afe3 2020-08-24)
```

If you don't have Rust installed, https://www.rust-lang.org/ has very detailed instructions on how to install it.

Rust releases a new version every 6 weeks and language development moves faster than other programming languages. It is common for the Rust packages provided by common package managers to lag behind the latest Rust release by several releases. For that reason, use of the rustup tool for managing Rust is highly recommended.

If you are a security paranoid individual and don't want to follow the official rustup install instructions involving a curl | sh (your paranoia is understood), you can find instructions for alternative installation methods at https://github.com/rust-lang/rustup.rs/#other-installation-methods.

### 2.3.2 Other System Dependencies

You will need a working C compiler/toolchain in order to build some Rust crates and their dependencies. If Rust cannot find a C compiler, it should print a message at build time and give you instructions on how to install one.

There is a known issue with PyOxidizer on Fedora 30+ that will require you to install the libxcrypt-compat package to avoid an error due to a missing libcrypt.so.1 file. See https://github.com/indygreg/PyOxidizer/ issues/89 for more info.

### 2.3.3 Installing PyOxidizer

PyOxidizer can be installed from its latest published crate:

\$ cargo install pyoxidizer

From a Git repository using cargo:

Or by cloning the Git repository and building the project locally:

```
$ git clone https://github.com/indygreg/PyOxidizer.git
$ cd PyOxidizer
$ cargo install --path pyoxidizer
```

**Note:** PyOxidizer's project policy is for the main branch to be stable. So it should always be relatively safe to use main instead of a released version.

**Danger:** A cargo build from the repository root directory will likely fail due to how some of the Rust crates are configured.

See Using Cargo with PyOxidizer Source Checkouts for instructions on how to invoke cargo.

Once the pyoxidizer executable is installed, try to run it:

```
$ pyoxidizer
PyOxidizer 0.8-pre
Gregory Szorc <gregory.szorc@gmail.com>
Build and distribute Python applications
USAGE:
        pyoxidizer [FLAGS] [SUBCOMMAND]
...
```

Congratulations, PyOxidizer is installed! Now let's move on to using it.

# 2.4 High-Level Project Lifecycle

PyOxidizer exposes various functionality through the interaction of pyoxidizer commands and configuration files.

The first step of any project is to create it. This is achieved with a pyoxidizer init-\* command to create files required by PyOxidizer.

After that, various pyoxidizer commands can be used to evaluate configuration files and perform actions from the evaluated file. PyOxidizer provides functionality for building binaries, installing files into a directory tree, and running the results of build actions.

# 2.5 Your First PyOxidizer Project

The pyoxidizer init-config-file command will create a new PyOxidizer configuration file in a directory of your choosing:

\$ pyoxidizer init-config-file pyapp

This should have printed out details on what happened and what to do next. If you actually ran this in a terminal, hopefully you don't need to continue following the directions here as the printed instructions are sufficient! But if you aren't, keep reading.

The default configuration created by pyoxidizer init-config-file will produce an executable that embeds Python and starts a Python REPL by default. Let's test that:

```
$ cd pyapp
$ pyoxidizer run
resolving 1 targets
resolving target exe
...
Compiling pyapp v0.1.0 (/tmp/pyoxidizer.nv7QvpNPRgL5/pyapp)
Finished dev [unoptimized + debuginfo] target(s) in 26.07s
writing executable to /home/gps/src/pyapp/build/x86_64-unknown-linux-gnu/debug/exe/
-pyapp
>>>
```

If all goes according to plan, you just started a Rust executable which started a Python interpreter, which started an interactive Python debugger! Try typing in some Python code:

>>> print("hello, world")
hello, world

It works!

(To exit the REPL, press CTRL+d or CTRL+z.)

Continue reading *The pyoxidizer Command Line Tool* to learn more about the pyoxidizer tool. Or read on for a preview of how to customize your application's behavior.

# 2.6 The pyoxidizer.bzl Configuration File

The most important file for a PyOxidizer project is the pyoxidizer.bzl configuration file. This is a Starlark file evaluated in a context that provides special functionality for PyOxidizer.

Starlark is a Python-like interpreted language and its syntax and semantics should be familiar to any Python programmer.

From a high-level, PyOxidizer's configuration files define named targets, which are callable functions associated with a name - the *target* - that resolve to an entity. For example, a configuration file may define a build\_exe() function which returns an object representing a standalone executable file embedding Python. The pyoxidizer build command can be used to evaluate just that target/function.

Target functions can call out to other target functions. For example, there may be an install target that creates a set of files composing a full application. Its function may evaluate the exe target to produce an executable file.

See *Configuration Files* for comprehensive documentation of pyoxidizer.bzl files and their semantics.

# 2.7 Customizing Python and Packaging Behavior

Embedding Python in a Rust executable and starting a REPL is cool and all. But you probably want to do something more exciting.

The autogenerated pyoxidizer.bzl file created as part of running pyoxidizer init-config-file defines how your application is configured and built. It controls everything from what Python distribution to use, which Python packages to install, how the embedded Python interpreter is configured, and what code to run in that interpreter.

Open pyoxidizer.bzl in your favorite editor and find the commented lines assigning to python\_config. run\_mode. Let's uncomment or add a line to match the following:

python\_config.run\_mode = "eval:import uuid; print(uuid.uuid4())"

We're now telling the interpreter to run the Python statement eval (import uuid; print (uuid.uuid4()) when it starts. Test that out:

```
$ pyoxidizer run
...
Compiling pyapp v0.1.0 (/home/gps/src/pyapp)
Finished dev [unoptimized + debuginfo] target(s) in 3.92s
Running `target/debug/pyapp`
writing executable to /home/gps/src/pyapp/build/x86_64-unknown-linux-gnu/debug/exe/
$$ pyapp
96f776c8-c32d-48d8-8c1c-aef8a735f535
```

It works!

This is still pretty trivial. But it demonstrates how the pyoxidizer.bzl is used to influence the behavior of built executables.

Let's do something a little bit more complicated, like package an existing Python application!

Find the exe = dist.to\_python\_executable ( line in the pyoxidizer.bzl file. Let's add a new line to make\_exe() just below where exe is assigned:

```
for resource in exe.pip_install(["pyflakes==2.2.0"]):
    resource.add_location = "in-memory"
    exe.add_python_resource(resource)
```

In addition, set the python\_config.run\_mode attribute to execute pyflakes:

python\_config.run\_mode = "eval:from pyflakes.api import main; main()"

Now let's try building and running the new configuration:

```
$ pyoxidizer run -- --help
...
Compiling pyapp v0.1.0 (/home/gps/src/pyapp)
Finished dev [unoptimized + debuginfo] target(s) in 5.49s
writing executable to /home/gps/src/pyapp/build/x86_64-unknown-linux-gnu/debug/exe/
→pyapp
Usage: pyapp [options]
Options:
--version show program's version number and exit
-h, --help show this help message and exit
```

You've just produced an executable for pyflakes!

There are far more powerful packaging and configuration settings available. Read all about them at *Configuration Files* and *Packaging User Guide*. Or continue on to *The pyoxidizer Command Line Tool* to learn more about the pyoxidizer tool.

# CHAPTER 3

# The pyoxidizer Command Line Tool

The pyoxidizer command line tool is a frontend to the various functionality of PyOxidizer. See *Components* for more on the various components of PyOxidizer.

## 3.1 Creating New Projects with init-config-file

The pyoxidizer init-config-file command will create a new pyoxidizer.bzl configuration file in the target directory:

\$ pyoxidizer init-config-file pyapp

This should have printed out details on what happened and what to do next.

# 3.2 Creating New Rust Projects with init-rust-project

The pyoxidizer init-rust-project command creates a minimal Rust project configured to build an application that runs an embedded Python interpreter from a configuration defined in a pyoxidizer.bzl configuration file. Run it by specifying the directory to contain the new project:

\$ pyoxidizer init-rust-project pyapp

This should have printed out details on what happened and what to do next.

The explicit creation of Rust projects to use PyOxidizer is not required. If your produced binaries only need to perform actions configurable via PyOxidizer configuration files (like running some Python code), an explicit Rust project isn't required, as PyOxidizer can auto-generate a temporary Rust project at build time.

But if you want to supplement the behavior of the binaries built with Rust, an explicit and persisted Rust project can facilitate that. For example, you may want to run custom Rust code before, during, and after a Python interpreter runs in the process.

See Rust Projects for more on the composition of Rust projects.

# 3.3 Adding PyOxidizer to an Existing Project with add

Do you have an existing Rust project that you want to add an embedded Python interpreter to? PyOxidizer can help with that too! The pyoxidizer add command can be used to add an embedded Python interpreter to an existing Rust project. Simply give the directory to a project containing a Cargo.toml file:

```
$ cargo init myrustapp
Created binary (application) package
$ pyoxidizer add myrustapp
```

This will add required files and make required modifications to add an embedded Python interpreter to the target project.

**Important:** It is highly recommended to have the destination project under version control so you can see what changes are made by pyoxidizer add and so you can undo any unwanted changes.

**Danger:** This command isn't very well tested. And results have been known to be wrong. If it doesn't *just work*, you may want to run pyoxidizer init and incorporate relevant files into your project manually. Sorry for the inconvenience.

# 3.4 Building PyObject Projects with build

The pyoxidizer build command is probably the most important and used pyoxidizer command. This command evaluates a pyoxidizer.bzl configuration file by resolving *targets* in it.

By default, the default *target* in the configuration file is resolved. However, callers can specify a list of explicit *targets* to resolve. e.g.:

```
# Resolve the default target.
$ pyoxidizer build
# Resolve the "exe" and "install" targets, in that order.
$ pyoxidizer build exe install
```

PyOxidizer configuration files are effectively defining a build system, hence the name *build* for the command to resolve *targets* within.

## 3.5 Running the Result of Building with run

Target functions in PyOxidizer configuration files return objects that may be *runnable*. For example, a *PythonEx*ecutable returned by a target function that defines a Python executable binary can be *run* by executing a new process.

The pyoxidizer run command is used to attempt to *run* an object returned by a build target. It is effectively pyoxidizer build followed by *running* the returned object. e.g.:

```
# Run the default target.
$ pyoxidizer run
# Run the "install" target.
$ pyoxidizer run --target install
```

# 3.6 Analyzing Produced Binaries with analyze

The pyoxidizer analyze command is a generic command for analyzing the contents of executables and libraries. While it is generic, its output is specifically tailored for PyOxidizer.

Run the command with the path to an executable. For example:

\$ pyoxidizer analyze build/apps/myapp/x86\_64-unknown-linux-gnu/debug/myapp

Behavior is dependent on the format of the file being analyzed. But the general theme is that the command attempts to identify the run-time requirements for that binary. For example, for ELF binaries it will list all shared library dependencies and analyze glibc symbol versions and print out which Linux distributions it thinks the binary is compatible with.

Note: pyoxidizer analyze is not yet implemented for all executable file types that PyOxidizer supports.

# 3.7 Inspecting Python Distributions

PyOxidizer uses special pre-built Python distributions to build binaries containing Python.

These Python distributions are zstandard compressed tar files. Zstandard is a modern compression format that is really, really, really good. (PyOxidizer's maintainer also maintains Python bindings to zstandard and has written about the benefits of zstandard on his blog. You should read that blog post so you are enlightened on how amazing zstandard is.) But because zstandard is relatively new, not all systems have utilities for decompressing that format yet. So, the pyoxidizer python-distribution-extract command can be used to extract the zstandard compressed tar archive to a local filesystem path.

Python distributions contain software governed by a number of licenses. This of course has implications for application distribution. See *Licensing Considerations* for more.

The pyoxidizer python-distribution-licenses command can be used to inspect a Python distribution archive for information about its licenses. The command will print information about the licensing of the Python distribution itself along with a per-extension breakdown of which libraries are used by which extensions and which licenses apply to what. This command can be super useful to audit for license usage and only allow extensions with licenses that you are legally comfortable with.

For example, the entry for the readline extension shows that the extension links against the neurses and readline libraries, which are governed by the X11, and GPL-3.0 licenses:

```
readline
------
Dependency: ncurses
Link Type: library
Dependency: readline
Link Type: library
Licenses: GPL-3.0, X11
License Info: https://spdx.org/licenses/GPL-3.0.html
License Info: https://spdx.org/licenses/X11.html
```

Note: The license annotations in Python distributions are best effort and can be wrong. They do not constitute a

legal promise. Paranoid individuals may want to double check the license annotations by verifying with source code distributions, for example.

# 3.8 Debugging Resource Scanning and Identification with find-resources

The pyoxidizer find-resources command can be used to scan for resources in a given source and then print information on what's found.

PyOxidizer's packaging functionality scans directories and files and classifies them as Python resources which can be operated on. See *Resource Types*. PyOxidizer's run-time importer/loader (*oxidized\_importer Python Extension*) works by reading a pre-built index of known resources. This all works in contrast to how Python typically works, which is to put a bunch of files in directories and let the built-in importer/loader figure it out by dynamically probing for various files.

Because PyOxidizer has introduced structure where it doesn't exist in Python and because there are many subtle nuances with how files are classified, there can be bugs in PyOxidizer's resource scanning code.

The pyoxidizer find-resources command exists to facilitate debugging PyOxidizer's resource scanning code.

Simply give the command a path to a directory or Python wheel archive and it will tell you what it discovers. e.g.:

Or give it the path to a site-packages directory:

```
$ pyoxidizer find-resources ~/.pyenv/versions/3.8.6/lib/python3.8/site-packages
...
```

This command needs to use a Python distribution so it knows what file extensions correspond to Python extensions, etc. By default, it will download one of the *built-in distributions* that is compatible with the current machine and use that. You can specify a --distributions-dir to use to cache downloaded distributions:

```
$ pyoxidizer find-resources --distributions-dir distributions /usr/lib/python3.8
...
```

# CHAPTER 4

# **Configuration Files**

PyOxidizer uses Starlark files to configure run-time behavior.

Starlark is a dialect of Python intended to be used as a configuration language and the syntax should be familiar to any Python programmer.

This documentation section contains both a high-level overview of the configuration files and their semantics as well as low-level documentation for every type and function in the Starlark dialect.

# 4.1 Automatic File Location Strategy

If the PYOXIDIZER\_CONFIG environment variable is set, the path specified by this environment variable will be used as the location of the Starlark configuration file.

If the OUT\_DIR environment variable is set (we're building from the context of a Rust project), the ancestor directories will be searched for a pyoxidizer.bzl file and the first one found will be used.

Otherwise, PyOxidizer will look for a pyoxidizer.bzl file starting in either the current working directory or from the directory containing the pyembed crate and then will traverse ancestor directories until a file is found.

If no configuration file is found, an error occurs.

# 4.2 Concepts

### 4.2.1 Processing

A configuration file is evaluated in a custom Starlark *dialect* which provides primitives used by PyOxidizer. This dialect provides some well-defined global variables (defined in UPPERCASE) as well as some types and functions that can be constructed and called. See *Global Symbols* for a full list of what's available to the Starlark environment.

Since Starlark is effectively a subset of Python, executing a PyOxidizer configuration file is effectively running a sandboxed Python script. It is conceptually similar to running python setup.py to build a Python package.

As functions within the Starlark environment are called, PyOxidizer will perform actions as described by those functions.

### 4.2.2 Targets

PyOxidizer configuration files are composed of functions registered as named *targets*. You define a function that does something then register it as a target by calling the *register\_target()* global function provided by our Starlark dialect. e.g.:

```
def get_python_distribution():
    return default_python_distribution()
register_target("dist", get_python_distribution)
```

When a configuration file is evaluated, PyOxidizer attempts to *resolve* an ordered list of *targets* This list of targets is either specified by the end-user or is derived from the configuration file. The first register\_target() target or the last register\_target() call passing default=True is the default target.

When evaluated in *Rust build script mode* (typically via pyoxidizer run-build-script), the default target will be the one specified by the last register\_target() call passing default\_build\_script=True, or the default target if no target defines itself as the default build script target.

PyOxidizer calls the registered target functions in order to resolve the requested set of targets.

Target functions can depend on other targets and dependent target functions will automatically be called and have their return value passed as an argument to the target function depending on it. See *register\_target()* for more.

The value returned by a target function is special. If that value is one of the special types defined by our Starlark dialect (e.g. *PythonDistribution* or *PythonExecutable*), PyOxidizer will attempt to invoke special functionality depending on the run mode. For example, when running pyoxidizer build to *build* a target, PyOxidizer will invoke any *build* functionality on the value returned by a target function, if present. For example, a PythonExecutable's *build* functionality would compile an executable binary embedding Python.

### 4.2.3 Python Distributions Provide Python

The *PythonDistribution* Starlark type defines a Python distribution. A Python distribution is an entity which contains a Python interpreter, Python standard library, and which PyOxidizer knows how to consume and integrate into a new binary.

PythonDistribution instances are arguably the most important type in configuration files because without them you can't perform Python packaging actions or construct binaries with Python embedded.

Instances of PythonDistribution are typically constructed from *default\_python\_distribution()* and are registered as their own target, since multiple targets may want to reference the distribution instance:

```
def make_dist():
    return default_python_distribution()
register_target("dist", make_dist)
```

### 4.2.4 Python Executables Run Python

The *PythonExecutable* Starlark type defines an executable file embedding Python. Instances of this type are used to build an executable file (and possibly other files needed by it) that contains an embedded Python interpreter and other resources required by it.

Instances of PythonExecutable are derived from a PythonDistribution instance via the *PythonDistribution.to\_python\_executable()* method. There is typically a standalone function/target in config files for doing this.

### 4.2.5 Python Resources

At run-time, Python interpreters need to consult *resources* like Python module source and bytecode as well as resource/data files. We refer to all of these as *Python Resources*.

Configuration files represent Python Resources via the following types:

- PythonModuleSource
- PythonPackageResource
- PythonPackageDistributionResource
- PythonExtensionModule

### 4.2.6 Specifying Resource Locations

Various functionality relates to the concept of a *resource location*, or where a resource should be loaded from at run-time. See *Managing How Resources are Added* for more.

Resource locations are represented as strings in Starlark. The mapping of strings to resource locations is as follows:

**in-memory** Load the resource from memory.

filesystem-relative:<prefix> Install and load the resource from a filesystem relative path to the build binary. e.g. filesystem-relative:lib will place resources in the lib/ directory next to the build binary.

## 4.3 Resource Attributes Influencing Adding

Individual Starlark values representing resources expose various attributes prefixed with add\_ which influence what happens when that resource is added to a resource collector. These attributes are derived from the *PythonPackaging-Policy* attached to the entity creating the resource. But they can be modified by Starlark code before the resource is added to a collection.

The following sections describe each attribute that influences how the resource is added to a collection.

#### 4.3.1 add\_include

This bool attribute defines a yes/no filter for whether to actually add this resource to a collection. If a resource with .add\_include = False is added to a collection, that add is processed as a no-op and no change is made.

#### 4.3.2 add\_location

This string attributes defines the primary location this resource should be added to and loaded from at run-time.

It can be set to the following values:

in-memory The resource should be loaded from memory.

For Python modules and resource files, the module is loaded from memory using 0-copy by the custom module importer.

For Python extension modules, the extension module may be statically linked into the built binary or loaded as a shared library from memory (the latter is not supported on all platforms).

**filesystem-relative:<prefix>** The resource is materialized on the filesystem relative to the built entity and loaded from the filesystem at run-time.

<prefix> here is a directory prefix to place the resource in. . (e.g. filesystem-relative:.) can be
used to denote the same directory as the built entity.

### 4.3.3 add\_location\_fallback

This string or None value attribute is equivalent to add\_location except it only comes into play if the location specified by add\_location could not be satisfied.

Some resources (namely Python extension modules) cannot exist in all locations. Setting this attribute to a different location gives more flexibility for packaging resources with location constraints.

### 4.3.4 add\_source

This bool attribute defines whether to add source code for a Python module.

For Python modules, typically only bytecode is required at run-time. For some applications, the presence of source code doesn't provide sufficient value or isn't desired since the application developer may want to obfuscate the source code. Setting this attribute to False prevents Python module source code from being added.

### 4.3.5 add\_bytecode\_optimization\_level\_zero

This bool attributes defines whether to add Python bytecode for optimization level 0 (the default optimization level).

If True, Python source code will be compiled to bytecode at build time.

The default value is whatever PythonPackagingPolicy.bytecode\_optimize\_level\_zero is set to.

### 4.3.6 add\_bytecode\_optimization\_level\_one

This bool attributes defines whether to add Python bytecode for optimization level 1.

The default value is whatever PythonPackagingPolicy.bytecode\_optimize\_level\_one is set to.

### 4.3.7 add\_bytecode\_optimization\_level\_two

This bool attributes defines whether to add Python bytecode for optimization level 2.

The default value is whatever PythonPackagingPolicy.bytecode\_optimize\_level\_two is set to.

# 4.4 Global Symbols

This document lists every single global type, variable, and function available in PyOxidizer's Starlark execution environment.

In addition to the symbols provided by PyOxidizer's Starlark dialect, there are also the Starlark built-ins.

### 4.4.1 Global Types

PyOxidizer's Starlark dialect defines the following custom types:

*File* Represents a filesystem path and content.

*FileContent* Represents the content of a file on the filesystem.

(Unlike *File*, this does not track the filename internally.)

FileManifest Represents a mapping of filenames to file content.

PythonDistribution Represents an implementation of Python.

Used for embedding into binaries and running Python code.

PythonEmbeddedResources Represents resources made available to a Python interpreter.

*PythonExecutable* Represents an executable file containing a Python interpreter.

PythonExtensionModule Represents a compiled Python extension module.

PythonInterpreterConfig Represents the configuration of a Python interpreter.

PythonPackageDistributionResource Represents a file containing Python package distribution metadata.

PythonPackageResource Represents a non-module resource data file.

PythonPackagingPolicy Represents a policy controlling how Python resources are added to a binary.

*PythonModuleSource* Represents a . py file containing Python source code.

### 4.4.2 Global Constants

The Starlark execution environment defines various variables in the global scope which are intended to be used as read-only constants. The following sections describe these variables.

#### BUILD\_TARGET\_TRIPLE

The string Rust target triple that we're currently building for. Will be a value like x86\_64-unknown-linux-gnu or x86\_64-pc-windows-msvc. Run rustup target list to see a list of targets.

#### CONFIG\_PATH

The string path to the configuration file currently being evaluated.

#### CONTEXT

Holds build context. This is an internal variable and accessing it will not provide any value.

#### CWD

The current working directory. Also the directory containing the active configuration file.

### 4.4.3 Global Functions

PyOxidizer's Starlark dialect defines the following global functions: default\_python\_distribution() Obtain the default PythonDistribution for the active build configuration. glob() Collect files from the filesystem. register\_target() Register a named target that can be built. resolve\_target() Build/resolve a specific named target. resolve\_targets() Triggers resolution of requested build targets. set\_build\_path() Set the filesystem path to use for writing files during evaluation.

# 4.5 Functions for Manipulating Global State

### 4.5.1 set\_build\_path()

Configure the directory where build artifacts will be written.

Build artifacts include Rust build state, files generated by PyOxidizer, staging areas for built binaries, etc.

If a relative path is passed, it is interpreted as relative to the directory containing the configuration file.

The default value is \$CWD/build.

**Important:** This needs to be called before functionality that utilizes the build path, otherwise the default value will be used.

## 4.6 Functions for Managing Targets

#### 4.6.1 register\_target()

Registers a named target that can be resolved by the configuration file.

A target consists of a string name, callable function, and an optional list of targets it depends on.

The callable may return one of the types defined by this Starlark dialect to facilitate additional behavior, such as how to build and run it.

Arguments:

name (string) The name of the target being register.

fn (function) A function to call when the target is resolved.

**depends** (list of string or None) List of target strings this target depends on. If specified, each dependency will be evaluated in order and its returned value (possibly cached from prior evaluation) will be passed as a positional argument to this target's callable.

- **default** (bool) Indicates whether this should be the default target to evaluate. The last registered target setting this to True will be the default. If no target sets this to True, the first registered target is the default.
- default\_build\_script (bool) indicates whether this should be the default target to evaluate when run from
   the context of a Rust build script (e.g. from pyoxidizer run-build-script. It has the same semantics
   as default.

**Note:** It would be easier for target functions to call resolve\_target() within their implementation. However, Starlark doesn't allow recursive function calls. So invocation of target callables must be handled specially to avoid this recursion.

### 4.6.2 resolve\_target()

Triggers resolution of a requested build target.

This function resolves a target registered with register\_target() by calling the target's registered function or returning the previously resolved value from calling it.

This function should be used in cases where 1 target depends on the resolved value of another target. For example, a target to create a FileManifest may wish to add a PythonExecutable that was resolved from another target.

#### 4.6.3 resolve\_targets()

Triggers resolution of requested build targets.

This is usually the last meaningful line in a config file. It triggers the building of targets which have been requested to resolve by whatever is invoking the config file.

## 4.7 Functions for Interacting with the Filesystem

### 4.7.1 glob()

The glob () function resolves file patterns to a *FileManifest*.

This function accepts the following arguments:

- **include** (list of string) Defines file patterns that will be matched using the glob Rust crate. If patterns begin with / or look like a filesystem absolute path, they are absolute. Otherwise they are evaluated relative to the directory of the current config file.
- **exclude** (list of string or None) File patterns used to exclude files from the result. All patterns in include are evaluated before exclude.
- strip\_prefix (string or None) Prefix to strip from the beginning of matched files. strip\_prefix is
   stripped after include and exclude are processed.

Returns a FileManifest.

### 4.8 FileContent

This type represents the content of a single file.

### 4.9 FileManifest

The FileManifest type represents a set of files and their content.

FileManifest instances are used to represent things like the final filesystem layout of an installed application.

Conceptually, a FileManifest is a dict mapping relative paths to file content.

### 4.9.1 Methods

#### FileManifest.add\_manifest()

This method overlays another FileManifest on this one. If the other manifest provides a path already in this manifest, its content will be replaced by what is in the other manifest.

#### FileManifest.add\_python\_resource()

This method adds a Python resource to a FileManifest instance in a specified directory prefix.

Arguments:

prefix (string) Directory prefix to add resource to.

value (various) A Python resource instance to add. e.g. PythonModuleSource or PythonPackageResource.

This method can be used to place the Python resources derived from another type or action in the filesystem next to an application binary.

#### FileManifest.add\_python\_resources()

This method adds an iterable of Python resources to a FileManifest instance in a specified directory prefix. This is effectively a wrapper for for value in values: self.add\_python\_resource(prefix, value).

For example, to place the Python distribution's standard library Python source modules in a directory named lib:

```
m = FileManifest()
dist = default_python_distribution()
for resource in dist.python_resources():
    if type(resource) == "PythonModuleSource":
        m.add_python_resource("lib", resource)
```

#### FileManifest.install()

This method writes the content of the FileManifest to a directory specified by path. The path is evaluated relative to the path specified by BUILD\_PATH.

If replace is True (the default), the destination directory will be deleted and the final state of the destination directory should exactly match the state of the FileManifest.

### 4.10 File

This type represents a concrete file in an abstract filesystem. The file has a path and content.

Instances can be constructed by calling methods that emit resources with a *PythonPackagingPolicy* having *file\_scanner\_emit\_files* set to True.

### 4.10.1 Attributes

The following sections describe the attributes available on each instance.

#### path

#### (string)

The filesystem path represented. Typically relative. Doesn't have to correspond to a valid, existing file on the filesystem.

#### is\_executable

(bool)

Whether the file is executable.

#### add\_\*

(various) See Resource Attributes Influencing Adding.

## 4.11 PythonDistribution

The PythonDistribution type defines a Python distribution. A Python distribution is an entity that defines an implementation of Python. This entity can be used to create a binary embedding or running Python and can be used to execute Python code.

### 4.11.1 Constructors

Instances of PythonDistribution can be constructed via a constructor function or via *de-fault\_python\_distribution()*.

#### default\_python\_distribution()

Resolves the default PythonDistribution.

The following named arguments are accepted:

flavor (string) Denotes the *distribution* flavor. See the section below on allowed values.

Defaults to standalone.

**build\_target** (string) Denotes the machine target triple that we're building for.

Defaults to the value of the BUILD\_TARGET global constant.

python\_version (string) X.Y major.minor string denoting the Python release version to use.

Supported values are 3.8 and 3.9.

Defaults to 3.8.

- flavor is a string denoting the distribution *flavor*. Values can be one of the following:
- **standalone** A distribution produced by the python-build-standalone project. The distribution may be statically or dynamically linked, depending on the build\_target and availability. This option effectively chooses the best available standalone\_dynamic or standalone\_static option.

This option is effectively standalone\_dynamic for all targets except musl libc, where it is effectively standalone\_static.

**standalone\_dynamic** This is like standalone but guarantees the distribution is dynamically linked against various system libraries, notably libc. Despite the dependence on system libraries, binaries built with these distributions can generally be run in most environments.

This flavor is available for all supported targets except musl libc.

standalone\_static This is like standalone but guarantees the distribution is statically linked and has minimal - possibly none - dependencies on system libraries.

On Windows, the Python distribution does not export Python's symbols, meaning that it is impossible to load dynamically linked Python extensions with it.

On musl libc, statically linked distributions do not support loading extension modules existing as shared libraries.

This flavor is only available for Windows and musl libc targets.

**Note:** The *static* versus *dynamic* terminology refers to the linking of the overall distribution, not libpython or the final produced binaries.

The pyoxidizer binary has a set of known distributions built-in which are automatically available and used by this function. Typically you don't need to build your own distribution or change the distribution manually.

#### PythonDistribution()

Construct a PythonDistribution from arguments.

The following arguments are accepted:

**sha256** (string) The SHA-256 of the distribution archive file.

local\_path (string) Local filesystem path to the distribution archive.

url (string) URL from which a distribution archive can be obtained using an HTTP GET request.

flavor (string) The distribution flavor. Must be standalone.

A Python distribution is a zstandard-compressed tar archive containing a specially produced build of Python. These distributions are typically produced by the python-build-standalone project. Pre-built distributions are available at https://github.com/indygreg/python-build-standalone/releases.

A distribution is defined by a location, and a hash.

One of local\_path or url MUST be defined.

Examples:

```
linux = PythonDistribution(
    sha256="11a53f5755773f91111a04f6070a6bc00518a0e8e64d90f58584abf02ca79081",
    local_path="/var/python-distributions/cpython-linux64.tar.zst"
)
macos = PythonDistribution(
    sha256="b46a861c05cb74b5b668d2ce44dcb65a449b9fef98ba5d9ec6ff6937829d5eec",
    url="https://github.com/indygreg/python-build-standalone/releases/download/
    +20190505/cpython-3.7.3-macos-20190506T0054.tar.zst"
)
```

### 4.11.2 Methods

#### PythonDistribution.python\_resources()

Returns a list of objects representing Python resources in this distribution. Returned values can be *PythonModule-Source*, *PythonExtensionModule*, *PythonPackageResource*, etc.

There may be multiple *PythonExtensionModule* with the same name.

#### PythonDistribution.make\_python\_interpreter\_config()

Obtain a PythonInterpreterConfig derived from the distribution.

The interpreter configuration automatically uses settings appropriate for the distribution.

#### PythonDistribution.make\_python\_packaging\_policy()

Obtain a PythonPackagingPolicy derived from the distribution.

The policy automatically uses settings globally appropriate for the distribution.

#### PythonDistribution.to\_python\_executable()

This method constructs a *PythonExecutable* instance. It essentially says *build an executable embedding Python from this distribution*.

The accepted arguments are:

- name (string) The name of the application being built. This will be used to construct the default filename of the
   executable.
- packaging\_policy (PythonPackagingPolicy) The packaging policy to apply to the executable builder.

This influences how Python resources from the distribution are added. It also influences future resource adds to the executable.

config (PythonInterpreterConfig) The default configuration of the embedded Python interpreter.

Default is what *PythonDistribution.make\_python\_interpreter\_config()* returns.

**Important:** Libraries that extension modules link against have various software licenses, including GPL version 3. Adding these extension modules will also include the library. This typically exposes your program to additional

licensing requirements, including making your application subject to that license and therefore open source. See *Licensing Considerations* for more.

# 4.12 PythonEmbeddedResources

The PythonEmbeddedResources type represents resources made available to a Python interpreter. The resources tracked by this type are consumed by the pyembed crate at build and run time. The tracked resources include:

- Python module source and bytecode
- Python package resources
- Shared library dependencies

While the type's name has *embedded* in it, resources referred to by this type may or may not actually be *embedded* in a Python binary or loaded directly from the binary. Rather, the term *embedded* comes from the fact that the data structure describing the resources is typically *embedded* in the binary or made available to an *embedded* Python interpreter.

Instances of this type are constructed by transforming a type representing a Python binary. e.g. *PythonExe-cutable.to\_embedded\_resources()*.

If this type is returned by a target function, its build action will write out files that represent the various resources encapsulated by this type. There is no run action associated with this type.

# 4.13 PythonExecutable

The PythonExecutable type represents an executable file containing the Python interpreter, Python resources to make available to the interpreter, and a default run-time configuration for that interpreter.

Instances are constructed from PythonDistribution instances using PythonDistribution.to\_python\_executable().

### 4.13.1 Methods

#### PythonExecutable.make\_python\_module\_source()

This method creates a PythonModuleSource instance suitable for use with the executable being built.

Arguments are as follows:

name (string) The name of the Python module. This is the fully qualified module name. e.g. foo or foo.bar.

**source** (string) Python source code comprising the module.

**is\_package (bool)** Whether the Python module is also a package. (e.g. the equivalent of a <u>\_\_\_\_\_\_</u>.py file or a module without a . in its name.

#### PythonExecutable.pip\_download()

This method runs pip download <args> with settings appropriate to target the executable being built.

This always uses --only-binary=:all:, forcing pip to only download wheel based packages.

This method accepts the following arguments:

args (list of string) Command line arguments to pass to pip download. Arguments will be added after default arguments added internally.

Returns a list of objects representing Python resources collected from wheels obtained via pip download.

#### PythonExecutable.pip\_install()

This method runs pip install <args> with settings appropriate to target the executable being built.

args List of strings defining raw process arguments to pass to pip install.

**extra\_envs** Optional dict of string key-value pairs constituting extra environment variables to set in the invoked pip process.

Returns a list of objects representing Python resources installed as part of the operation. The types of these objects can be *PythonModuleSource*, *PythonPackageResource*, etc.

The returned resources are typically added to a FileManifest or PythonExecutable to make them available to a packaged application.

#### PythonExecutable.read\_package\_root()

This method discovers resources from a directory on the filesystem.

The specified directory will be scanned for resource files. However, only specific named *packages* will be found. e.g. if the directory contains sub-directories foo/ and bar, you must explicitly state that you want the foo and/or bar package to be included so files from these directories will be read.

This rule is frequently used to pull in packages from local source directories (e.g. directories containing a setup.py file). This rule doesn't involve any packaging tools and is a purely driven by filesystem walking. It is primitive, yet effective.

This rule has the following arguments:

path (string) The filesystem path to the directory to scan.

packages (list of string) List of package names to include.

Filesystem walking will find files in a directory <path>/<value>/ or in a file <path>/<value>.py.

Returns a list of objects representing Python resources found in the virtualenv. The types of these objects can be PythonModuleSource, PythonPackageResource, etc.

The returned resources are typically added to a FileManifest or PythonExecutable to make them available to a packaged application.

#### PythonExecutable.read\_virtualenv()

This method attempts to read Python resources from an already built virtualenv.

**Important:** PyOxidizer only supports finding modules and resources populated via *traditional* means (e.g. pip install or python setup.py install). If .pth or similar mechanisms are used for installing modules, files may not be discovered properly.

It accepts the following arguments:

path (string) The filesystem path to the root of the virtualenv.

Python modules are typically in a lib/pythonX.Y/site-packages directory (on UNIX) or Lib/ site-packages directory (on Windows) under this path.

Returns a list of objects representing Python resources found in the virtualenv. The types of these objects can be PythonModuleSource, PythonPackageResource, etc.

The returned resources are typically added to a FileManifest or PythonExecutable to make them available to a packaged application.

#### PythonExecutable.setup\_py\_install()

This method runs python setup.py install against a package at the specified path.

It accepts the following arguments:

package\_path String filesystem path to directory containing a setup.py to invoke.

- extra\_envs={} Optional dict of string key-value pairs constituting extra environment variables to set in the invoked python process.
- extra\_global\_arguments=[] Optional list of strings of extra command line arguments to pass to python
   setup.py. These will be added before the install argument.

Returns a list of objects representing Python resources installed as part of the operation. The types of these objects can be PythonModuleSource, PythonPackageResource, etc.

The returned resources are typically added to a FileManifest or PythonExecutable to make them available to a packaged application.

#### PythonExecutable.add\_python\_resource()

This method registers a Python resource of various types with the instance.

It accepts a resource argument which can be a PythonModuleSource, PythonPackageResource, or PythonExtensionModule and registers that resource with this instance.

The following arguments are accepted:

**resource** The resource to add to the embedded Python environment.

This method is a glorified proxy to the various add\_python\_\* methods. Unlike those methods, this one accepts all types that are known Python resources.

#### PythonExecutable.add\_python\_resources()

This method registers an iterable of Python resources of various types. This method is identical to *PythonExe-cutable.add\_python\_resource()* except the argument is an iterable of resources. All other arguments are identical.

#### PythonExecutable.filter\_from\_files()

This method filters all embedded resources (source modules, bytecode modules, and resource names) currently present on the instance through a set of resource names resolved from files.

This method accepts the following arguments:

**files** (array of string) List of filesystem paths to files containing resource names. The file must be valid UTF-8 and consist of a \n delimited list of resource names. Empty lines and lines beginning with # are ignored.

glob\_files (array of string) List of glob matching patterns of filter files to read. \* denotes all files in a directory.
 \*\* denotes recursive directories. This uses the Rust glob crate under the hood and the documentation for that
 crate contains more pattern matching info.

The files read by this argument must be the same format as documented by the files argument.

All defined files are first read and the resource names encountered are unioned into a set. This set is then used to filter entities currently registered with the instance.

#### PythonExecutable.to\_embedded\_resources()

Obtains a *PythonEmbeddedResources* instance representing resources to be made available to the Python interpreter. See the *PythonEmbeddedResources* type documentation for more.

## 4.14 PythonExtensionModule

This type represents a compiled Python extension module.

## 4.14.1 Attributes

The following sections describe the attributes available on each instance.

#### name

#### (string)

Unique name of the module being provided.

#### is\_stdlib

(bool)

Whether this module is part of the Python standard library (part of the Python distribution).

#### add\_\*

(various)

See Resource Attributes Influencing Adding.

## 4.15 PythonInterpreterConfig

This type configures the default behavior of the embedded Python interpreter.

Embedded Python interpreters are configured and instantiated using a Rust pyembed::OxidizedPythonInterpreterConfig data structure. The pyembed crate defines a default instance of this data structure with parameters defined by the settings in this type.

**Note:** If you are writing custom Rust code and constructing a custom pyembed::OxidizedPythonInterpreterConfig instance and don't use the default instance, this config type is not relevant to you and can be omitted from your config file.

**Danger:** Some of the settings exposed by Python's initialization APIs are extremely low level and brittle. Various combinations can cause the process to crash/exit ungracefully. Be very cautious when setting these low-level settings.

## 4.15.1 Constructors

Instances are constructed by calling *PythonDistribution.make\_python\_interpreter\_config()*.

## 4.15.2 Attributes

The PythonInterpreterConfig state is managed via attributes.

There are a ton of attributes and most attributes are not relevant to most applications. The bulk of the attributes exist to give full control over Python interpreter initialization.

## Attributes For Controlling pyembed Features

This section documents attributes for controlling features provided by the pyembed Rust crate, which manages the embedded Python interpreter at run-time.

These attributes provide features and level of control over embedded Python interpreters beyond what is possible with Python's initialization C API.

## raw\_allocator

(string)

Configures the low-level *raw* allocator used by Python. Internally, Python has its own allocator that manages pools of memory. But that allocator gets its memory from some other allocator. This attribute defines what that other allocator is. In Python C API speak, this defines the allocator for the PYMEM\_DOMAIN\_RAW allocator.

Accepted values are:

**system** Use the default allocator functions exposed to the binary (malloc(), free(), etc).

**jemalloc** Use the jemalloc allocator.

**rust** Use Rust's global allocator (whatever that may be).

The jemalloc allocator requires the jemalloc-sys crate to be available. A run-time error will occur if jemalloc is configured but this allocator isn't available.

**Important:** The rust allocator is not recommended because it introduces performance overhead. But it may help with debugging in some situations.

Default is jemalloc on non-Windows targets and system on Windows. (The jemalloc-sys crate doesn't work on Windows MSVC targets.)

### oxidized\_importer

(bool)

Whether to install the oxidized\_importer meta path importer (*oxidized\_importer Python Extension*) on sys. meta\_path during interpreter initialization.

Defaults to True.

#### filesystem\_importer

#### (bool)

Whether to install the standard library path-based importer for loading Python modules from the filesystem.

If not enabled, Python modules will not be loaded from the filesystem (via sys.path discovery): only modules indexed by oxidized\_importer will be loadable.

The filesystem importer is enabled automatically if *module\_search\_paths* is non-empty.

#### argvb

#### (bool)

Whether to expose a sys.argvb attribute containing bytes versions of process arguments.

On platforms where the process receives char \* arguments, Python normalizes these values to unicode and makes them available via sys.argv. On platforms where the process receives wchar\_t \* arguments, Python may interpret the bytes as a certain encoding. This encoding normalization can be lossy.

Enabling this feature will give Python applications access to the raw bytes values of arguments that are actually used. The single or double width bytes nature of the data is preserved.

Unlike sys.argv which may chomp off leading arguments depending on the Python execution mode, sys.argvb has all the arguments used to initialize the process. The first argument is always the executable.

#### sys\_frozen

#### (bool)

Controls whether to set the sys.frozen attribute to True. If false, sys.frozen is not set.

Default is False.

#### sys\_meipass

## (bool)

Controls whether to set the sys.\_MEIPASS attribute to the path of the executable.

Setting this and sys\_frozen to True will emulate the behavior of PyInstaller and could possibly help self-contained applications that are aware of PyInstaller also work with PyOxidizer.

Default is False.

#### terminfo\_resolution

#### (string)

Defines how the terminal information database (terminfo) should be configured.

See Terminfo Database for more about terminal databases.

#### Accepted values are:

dynamic Looks at the currently running operating system and attempts to do something reasonable.

For example, on Debian based distributions, it will look for the terminfo database in /etc/terminfo, /lib/terminfo, and /usr/share/terminfo, which is how Debian configures neurses to behave normally. Similar behavior exists for other recognized operating systems.

If the operating system is unknown, PyOxidizer falls back to looking for the terminfo database in well-known directories that often contain the database (like /usr/share/terminfo).

**none** The value none indicates that no configuration of the terminfo database path should be performed. This is useful for applications that don't interact with terminals. Using none can prevent some filesystem I/O at application startup.

**static:**<**path>** Indicates that a static path should be used for the path to the terminfo database.

This values consists of a : delimited list of filesystem paths that neurses should be configured to use. This value will be used to populate the TERMINFO\_DIRS environment variable at application run time.

terminfo is not used on Windows and this setting is ignored on that platform.

#### write\_modules\_directory\_env

#### (string or None)

Environment variable that defines a directory where modules-<UUID> files containing a n delimited list of loaded Python modules (from sys.modules) will be written upon interpreter shutdown.

If this setting is not defined or if the environment variable specified by its value is not present at run-time, no special behavior will occur. Otherwise, the environment variable's value is interpreted as a directory, that directory and any of its parents will be created, and a modules-<UUID> file will be written to the directory.

This setting is useful for determining which Python modules are loaded when running Python code.

#### run\_mode

#### (string)

This attribute controls what the Python interpreter should do after initializing.

Accepted values are:

**none** Don't do anything after initialization.

#### repl Run a Python REPL.

This should be equivalent to python.

module: <module> Run a named Python module as \_\_\_\_main\_\_\_.

This is roughly equivalent to python -m <module>.

python -m <module> has additional functionality compared to PyOxidizer. For example, Python will look for <module>.\_\_\_main\_\_\_ whereas PyOxidizer does not. Therefore an exact module name must be used.

eval:<code> Run Python code via eval().

This should be equivalent to python -c <code>.

An example value would be eval: import mymodule; mymodule.main().

file: <path> Run Python code in a file.

This should be equivalent to python <path>.

The filename is resolved at run-time using whatever mechanism the Python interpreter applies.

#### Attributes From PyPreConfig

Attributes in this section correspond to fields of the PyPreConfig C struct used to initialize the Python interpreter.

#### config\_profile

#### (string)

This attribute controls which set of default values to use for attributes that aren't explicitly defined. It effectively controls which C API to use to initialize the PyPreConfig instance.

Accepted values are:

isolated Use the isolated configuration.

This configuration is appropriate for applications existing in isolation and not behaving like python executables.

**python** Use the Python configuration.

This configuration is appropriate for applications attempting to behave like a python executable would.

#### allocator

(string or None)

Controls the value of PyPreConfig.allocator.

Accepted values are:

None Use the default.

not-set PYMEM\_ALLOCATOR\_NOT\_SET

default PYMEM\_ALLOCATOR\_DEFAULT

debug PYMEM\_ALLOCATOR\_DEBUG

malloc PYMEM\_ALLOCATOR\_MALLOC

malloc-debug PYMEM\_ALLOCATOR\_MALLOC\_DEBUG

py-malloc PYMEM\_ALLOCATOR\_PYMALLOC

### py-malloc-debug PYMEM\_ALLOCATOR\_PYMALLOC\_DEBUG

### configure\_locale

(bool or None) Controls the value of PyPreConfig.configure\_locale.

### coerce\_c\_locale

(string or None)
Controls the value of PyPreConfig.coerce\_c\_locale.
Accepted values are:
LC\_CTYPE Read LC\_CTYPE
C Coerce the C locale.

### coerce\_c\_locale\_warn

(bool or None)
Controls the value of PyPreConfig.coerce\_c\_locale\_warn.

#### development\_mode

(bool or None)
Controls the value of PyPreConfig.development\_mode.

#### isolated

(bool or None) Controls the value of PyPreConfig.isolated.

## legacy\_windows\_fs\_encoding

(bool or None)
Controls the value of PyPreConfig.legacy\_windows\_fs\_encoding.

#### parse\_argv

(bool or None) Controls the value of PyPreConfig.parse\_argv.

#### use\_environment

(bool or None) Controls the value of PyPreConfig.use\_environment.

#### utf8\_mode

(bool or None) Controls the value of PyPreConfig.utf8\_mode.

### Attributes From PyConfig

Attributes in this section correspond to fields of the PyConfig C struct used to initialize the Python interpreter.

#### base\_exec\_prefix

(string or None)
Controls the value of PyConfig.base\_exec\_prefix.

### base\_executable

(string or None) Controls the value of PyConfig.base\_exectuable.

#### base\_prefix

(string or None)
Controls the value of PyConfig.base\_prefix.

## buffered\_stdio

(bool or None) Controls the value of PyConfig.buffered\_stdio.

#### bytes\_warning

(string or None)

Controls the value of PyConfig.bytes\_warning.

Accepted values are:

- None
- none

- warn
- raise

#### check\_hash\_pycs\_mode

(string or None)

Controls the value of PyConfig.check\_hash\_pycs\_mode.

Accepted values are:

- None
- always
- never
- default

### configure\_c\_stdio

(bool or None)

 $Controls \ the \ value \ of \ PyConfig.configure\_c\_stdio.$ 

### dump\_refs

(bool or None)
Controls the value of PyConfig.dump\_refs.

#### exec\_prefix

(string or None)
Controls the value of PyConfig.exec\_prefix.

### executable

(string or None) Controls the value of PyConfig.executable.

## fault\_handler

(bool or None)
Controls the value of PyConfig.fault\_handler.

## filesystem\_encoding

(string or None)
Controls the value of PyConfig.filesystem\_encoding.

### filesystem\_errors

(string or None) Controls the value of PyConfig.filesystem\_errors.

#### hash\_seed

(int or None)
Controls the value of PyConfig.hash\_seed.
PyConfig.use\_hash\_seed will automatically be set if this attribute is defined.

#### home

(string or None) Controls the value of PyConfig.home.

#### import\_time

(bool or None) Controls the value of PyConfig.import\_time.

## inspect

(bool or None) Controls the value of PyConfig.inspect.

## install\_signal\_handlers

(bool or None) Controls the value of PyConfig.install\_signal\_handlers.

## interactive

(bool or None)

Controls the value of PyConfig.interactive.

## legacy\_windows\_stdio

(bool or None)

Controls the value of PyConfig.legacy\_windows\_stdio.

## malloc\_stats

(bool or None)

Controls the value of PyConfig.malloc\_stats.

## module\_search\_paths

(list[string] or None)

Controls the value of PyConfig.module\_search\_paths.

This value effectively controls the initial value of sys.path.

The special string <code>\$ORIGIN</code> in values will be expanded to the absolute path of the directory of the executable at run-time. For example, if the executable is /opt/my-application/pyapp, <code>\$ORIGIN</code> will expand to /opt/my-application and the value <code>\$ORIGIN/lib</code> will expand to /opt/my-application/lib.

Setting this to a non-empty value also has the side-effect of setting filesystem\_importer = True

### optimization\_level

(int or None)

Controls the value of PyConfig.optimization\_level.

Allowed values are:

- None
- 0
- 1
- 2

This setting is only relevant if write\_bytecode is True and Python modules are being imported from the filesystem using Python's standard filesystem importer.

## parser\_debug

(bool or None)

Controls the value of PyConfig.parser\_debug.

## pathconfig\_warnings

## (bool or None)

Controls the value of PyConfig.pathconfig\_warnings.

## prefix

(string or None)
Controls the value of PyConfig.prefix.

#### program\_name

(string or None)
Controls the value of PyConfig.program\_name.

## pycache\_prefix

(string or None)
Controls the value of PyConfig.pycache\_prefix.

## python\_path\_env

(string or None)
Controls the value of PyConfig.pythonpath\_env.

## quiet

(bool or None) Controls the value of PyConfig.quiet.

## run\_command

(string or None)
Controls the value of PyConfig.run\_command.

## run\_filename

(string or None)
Controls the value of PyConfig.run\_filename.

## run\_module

(string or None)
Controls the value of PyConfig.run\_module.

## show\_alloc\_count

(bool or None) Controls the value of PyConfig.show\_alloc\_count.

### show\_ref\_count

(bool or None)
Controls the value of PyConfig.show\_ref\_count.

### site\_import

(bool or None)
Controls the value of PyConfig.site\_import.
The site module is typically not needed for standalone/isolated Python applications.

## skip\_first\_source\_line

(bool or None) Controls the value of PyConfig.skip\_first\_source\_line.

## stdio\_encoding

(string or None)
Controls the value of PyConfig.stdio\_encoding.

#### stdio\_errors

(string or None)
Controls the value of PyConfig.stdio\_errors.

## tracemalloc

(bool or None) Controls the value of PyConfig.tracemalloc.

## user\_site\_directory

(bool or None)

Controls the value of PyConfig.user\_site\_directory.

#### verbose

(bool or None) Controls the value of PyConfig.verbose.

#### warn\_options

(list[string] or None)

Controls the value of PyConfig.warn\_options.

#### write\_bytecode

(bool or None)

Controls the value of PyConfig.write\_bytecode.

This only influences the behavior of Python standard path-based importer (controlled via filesystem\_importer).

#### x\_options

(list[string] or None)

Controls the value of PyConfig.xoptions.

## 4.15.3 Starlark Caveats

The PythonInterpreterConfig Starlark type is backed by a Rust data structure. And when attributes are retrieved, a copy of the underlying Rust struct field is returned.

This means that if you attempt to mutate a Starlark value (as opposed to assigning an attribute), the mutation won't be reflected on the underlying Rust data structure.

For example:

```
config = dist.make_python_interpreter_config()
# assigns vec!["foo", "bar"].
config.module_search_paths = ["foo", "bar"]
# Creates a copy of the underlying list and appends to that copy.
# The stored value of `module_search_paths` is still `["foo", "bar"]`.
config.module_search_paths.append("baz")
```

To append to a list, do something like the following:

```
value = config.module_search_paths
value.append("baz")
config.module_search_paths = value
```

## 4.16 PythonModuleSource

This type represents Python source modules, agnostic of location.

Instances can be constructed via *PythonExecutable.make\_python\_module\_source()* or by calling methods that emit Python resources.

## 4.16.1 Attributes

The following sections describe the attributes available on each instance.

## name

(string)

Fully qualified name of the module. e.g. foo.bar.

## source

(string)

The Python source code for this module.

## is\_package

(bool)

Whether this module is also a Python package (or sub-package).

## is\_stdlib

(bool)

Whether this module is part of the Python standard library (part of the Python distribution).

add\_\*

(various)

See Resource Attributes Influencing Adding.

## 4.17 PythonPackageResource

This type represents a resource \_file\_ in a Python package. It is effectively a named blob associated with a Python package. It is typically accessed using the importlib.resources API.

## 4.17.1 Attributes

The following sections describe the attributes available on each instance.

### package

(string)

Python package this resource is associated with.

#### name

(string) Name of this resource.

### is\_stdlib

(bool)

Whether this module is part of the Python standard library (part of the Python distribution).

### add\_\*

(various)

See Resource Attributes Influencing Adding.

## 4.18 PythonPackageDistributionResource

This type represents a named resource to make available as Python package distribution metadata. These files are typically accessed using the importlib.metadata API.

Each instance represents a logical file in a <package>-<version>.dist-info or <package>-<version>.egg-info directory. There are specifically named files that contain certain data. For example, a \*.dist-info/METADATA file describes high-level metadata about a Python package.

## 4.18.1 Attributes

The following sections describe the attributes available on each instance.

## package

(string)

Python package this resource is associated with.

#### name

(string)

Name of this resource.

#### is\_stdlib

(bool)

Whether this module is part of the Python standard library (part of the Python distribution).

#### add\_\*

(various) See *Resource Attributes Influencing Adding*.

## 4.19 PythonPackagingPolicy

When building a Python binary, there are various settings that control which Python resources are added, where they are imported from, and other various settings. This collection of settings is referred to as a *Python Packaging Policy*. These settings are represented by the PythonPackagingPolicy type.

## 4.19.1 Attributes

The following sections describe the attributes available on each instance.

### allow\_files

(bool)

Whether to allow the collection of generic *file* resources.

If false, all collected/packaged resources must be instances of concrete resource types (PythonModuleSource, PythonPackageResource, etc).

If true, *File* instances can be added to resource collectors.

## allow\_in\_memory\_shared\_library\_loading

(bool)

Whether to allow loading of Python extension modules and shared libraries from memory at run-time.

Some platforms (notably Windows) allow opening shared libraries from a memory address. This mode of opening shared libraries allows libraries to be embedded in binaries without having to statically link them. However, not every library works correctly when loaded this way.

This flag defines whether to enable this feature where supported. Its true value can be ignored if the target platform doesn't support loading shared library from memory.

## bytecode\_optimize\_level\_zero

(bool)

Whether to add Python bytecode at optimization level 0 (the default optimization level the Python interpreter compiles bytecode for).

### bytecode\_optimize\_level\_one

(bool)

Whether to add Python bytecode at optimization level 1.

### bytecode\_optimize\_level\_two

(bool)

Whether to add Python bytecode at optimization level 2.

#### extension\_module\_filter

(string)

The filter to apply to determine which extension modules to add. The following values are recognized:

all Every named extension module will be included.

**minimal** Return only extension modules that are required to initialize a Python interpreter. This is a very small set and various functionality from the Python standard library will not work with this value.

**no-libraries** Return only extension modules that don't require any additional libraries.

Most common Python extension modules are included. Extension modules like \_ssl (links against OpenSSL) and zlib are not included.

no-gpl Return only extension modules that do not link against GPL licensed libraries.

Not all Python distributions may annotate license info for all extensions or the libraries they link against. If license info is missing, the extension is not included because it *could* be GPL licensed. Similarly, the mechanism for determining whether a license is GPL is based on an explicit list of non-GPL licenses. This ensures new GPL licenses don't slip through.

Default is all.

## file\_scanner\_classify\_files

(bool)

Whether file scanning should attempt to classify files and emit typed resources corresponding to the detected file type.

If True, operations that emit resource objects (such as *PythonExecutable.pip\_install()*) will emit specific types for each resource flavor. e.g. *PythonModuleSource*, *PythonExtensionModule*, etc.

If False, the file scanner does not attempt to classify the type of a file and this rich resource types are not emitted.

Can be used in conjunction with *file\_scanner\_emit\_files*. If both are True, there will be a *File* and an optional non-file resource for each source file.

Default is True.

## file\_scanner\_emit\_files

#### (bool)

Whether file scanning should emit file resources for each seen file.

If True, operations that emit resource objects (such as *PythonExecutable.pip\_install()*) will emit *File* instances for each encountered file.

If False, *File* instances will not be emitted. Can be used in conjunction with *file\_scanner\_classify\_files*. Default is False.

### include\_classified\_resources

(bool)

Whether strongly typed, classified non-File resources have their add\_include attribute set to True by default. Default is True.

#### include\_distribution\_sources

(bool)

Whether to add source code for Python modules in the Python distribution.

Default is True.

### include\_distribution\_resources

(bool)

Whether to add Python package resources for Python packages in the Python distribution. Default is False.

## include\_file\_resources

(bool) Whether *File* resources have their add\_include attribute set to True by default. Default is False.

#### include\_non\_distribution\_sources

(bool)

Whether to add source code for Python modules not in the Python distribution.

## include\_test

### (bool)

Whether to add Python resources related to tests.

Not all files associated with tests may be properly flagged as such. This is a best effort setting.

Default is False.

#### resources\_location

#### (string)

The location that resources should be added to by default. Default is in-memory.

#### resources\_location\_fallback

(string or None)

The fallback location that resources should be added to if resources\_location fails.

Default is None.

#### preferred\_extension\_module\_variants

#### (dict<string, string>) (readonly)

Mapping of extension module name to variant name.

This mapping defines which preferred named variant of an extension module to use. Some Python distributions offer multiple variants of the same extension module. This mapping allows defining which variant of which extension to use when choosing among them.

Keys set on this dict are not reflected in the underlying policy. To set a key, call the set\_preferred\_extension\_module\_variant() method.

## 4.19.2 Methods

The following sections describe methods on PythonPackagingPolicy instances.

#### PythonPackagingPolicy.register\_resource\_callback()

This method registers a Starlark function to be called when resource objects are created. The passed function receives 2 arguments: this PythonPackagingPolicy instance and the resource (e.g. PythonModuleSource) that was created.

The purpose of the callback is to enable Starlark configuration files to mutate resources upon creation so they can globally influence how those resources are packaged.

#### PythonPackagingPolicy.set\_preferred\_extension\_module\_variant()

This method will set a preferred Python extension module variant to use. See the documentation for preferred\_extension\_module\_variants above for more.

It accepts 2 string arguments defining the extension module name and its preferred variant.

### PythonPackagingPolicy.set\_resource\_handling\_mode()

This method takes a string argument denoting the *resource handling mode* to apply to the policy. This string can have the following values:

**classify** Files are classified as typed resources and handled as such.

Only classified resources can be added by default.

files Files are handled as raw files (as opposed to typed resources).

Only files can be added by default.

This method is effectively a convenience method for bulk-setting multiple attributes on the instance given a behavior mode.

classify will configure the file scanner to emit classified resources, configure the add\_include attribute to only be True on classified resources, and will disable the addition of File resources on resource collectors.

files will configure the file scanner to only emit File resources, configure the add\_include attribute to True on File and *classified* resources, and will allow resource collectors to add File instances.

# CHAPTER 5

## Packaging User Guide

So you want to package a Python application using PyOxidizer? You've come to the right place to learn how! Read on for all the details on how to *oxidize* your Python application!

First, you'll need to install PyOxidizer. See Installing for instructions.

## 5.1 Creating a PyOxidizer Project

The process for *oxidizing* every Python application looks the same: you start by creating a new PyOxidizer configuration file via the pyoxidizer init-config-file command:

```
# Create a new configuration file in the directory "pyapp"
$ pyoxidizer init-config-file pyapp
```

Behind the scenes, PyOxidizer works by leveraging a Rust project to build binaries embedding Python. The autogenerated project simply instantiates and runs an embedded Python interpreter. If you would like your built binaries to offer more functionality, you can create a minimal Rust project to embed a Python interpreter and customize from there:

```
# Create a new Rust project for your application in ~/src/myapp.
$ pyoxidizer init-rust-project ~/src/myapp
```

The auto-generated configuration file and Rust project will launch a Python REPL by default. And the pyoxidizer executable will look in the current directory for a pyoxidizer.bzl configuration file. Let's test that the new configuration file or project works:

```
$ pyoxidizer run
...
Compiling pyapp v0.1.0 (/home/gps/src/pyapp)
Finished dev [unoptimized + debuginfo] target(s) in 53.14s
writing executable to /home/gps/src/pyapp/build/x86_64-unknown-linux-gnu/debug/exe/
→pyapp
>>>
```

If all goes according to plan, you just built a Rust executable which contains an embedded copy of Python. That executable started an interactive Python debugger on startup. Try typing in some Python code:

```
>>> print("hello, world")
hello, world
```

### It works!

(To exit the REPL, press CTRL+d or CTRL+z or import sys; sys.exit(0) from the REPL.)

Note: If you have built a Rust project before, the output from building a PyOxidizer application may look familiar to you. That's because under the hood Cargo - Rust's package manager and build system - is doing a lot of the work to build the application. If you are familiar with Rust development, you can use cargo build and cargo run directly. However, Rust's build system is only responsible for build binaries and some of the higher-level functionality from PyOxidizer's configuration files (such as application packaging) will likely not be performed unless tweaks are made to the Rust project's build.rs.

Now that we've got a new project, let's customize it to do something useful.

## 5.2 Packaging Primitives in pyoxidizer.bzl Files

PyOxidizer's run-time behavior is controlled by pyoxidizer.bzl Starlark (a Python-like language) configuration files. See *Configuration Files* for documentation on these files, including low-level API documentation.

This document gives a medium-level overview of the important Starlark types and functions and how they all interact.

## 5.2.1 Targets Define Actions

As detailed at *Targets*, a PyOxidizer configuration file is composed of named *targets*, which are functions returning an object that may have a build or run action attached. Commands like pyoxidizer build identify a target to evaluate then effectively walk the dependency graph evaluating dependent targets until the requested target is *built*.

## 5.2.2 Defining an Executable Embedding Python

In this example, we create an executable embedding Python:

```
def make_dist():
    return default_python_distribution()

def make_exe(dist):
    return dist.to_python_executable("myapp")

register_target("dist", make_dist)
register_target("exe", make_exe, depends=["dist"], default=True)
```

PythonDistribution.to\_python\_executable() accepts an optional PythonPackagingPolicy instance that influences how the executable is built and what resources are added where. See the *type documentation* for the list of parameters that can be influenced. Some of this behavior is described in the sections below. Other examples are provided throughout the *Packaging User Guide* documentation.

## 5.2.3 Configuring the Python Interpreter Run-Time Behavior

The *PythonInterpreterConfig* Starlark type configures the default behavior of the Python interpreter embedded in built binaries.

A PythonInterpreterConfig instance is associated with PythonExecutable instances when they are created. A custom instance can be passed into PythonDistribution.to\_python\_executable() to use non-default settings.

In this example (similar to above), we construct a custom PythonInterpreterConfig instance using nondefaults and then pass this instance into the constructed PythonExecutable:

```
def make_dist():
    return default_python_distribution()

def make_exe(dist):
    config = dist.make_python_interpreter_config()
    config.run_mode = "eval:print('hello, world')"
    return dist.to_python_executable("myapp", config=config)

register_target("dist", make_dist)
register_target("exe", make_exe, depends=["dist"], default=True)
```

The PythonInterpreterConfig type exposes a lot of modifiable settings. See the *API documentation* for the complete list. These settings include but are not limited to:

- Control of low-level Python interpreter settings, such as whether environment variables (like PYTHONPATH) should influence run-time behavior, whether stdio should be buffered, and the filesystem encoding to use.
- Whether to enable the importing of Python modules from the filesystem and what the initial value of sys.path should be.
- The memory allocator that the Python interpreter should use.
- What Python code to run when the interpreter is started.
- How the terminfo database should be located.

Many of these settings are not needed for most programs and the defaults are meant to be reasonable for most programs. However, some settings - such as the run\_\* arguments defining what Python code to run by default - are required by most configuration files.

## 5.2.4 Adding Python Packages to Executables

A just-created PythonExecutable Starlark type contains just the Python interpreter and standard library derived from the PythonDistribution from which it came. While you can use PyOxidizer to produce an executable containing just a normal Python *distribution* with nothing else, many people will want to add their own Python packages/code.

The Starlark environment defines various types for representing Python package resources. These include *Python-ModuleSource*, *PythonExtensionModule*, *PythonPackageDistributionResource*, and more.

Instances of these types can be created dynamically or by performing common Python packaging operations (such as invoking pip install) via various methods on PythonExecutable instances. These Python package resource instances can then be added to PythonExecutable instances so they are part of the built binary.

See Managing How Resources are Added and Packaging Python Files for more on this topic, including many examples.

## 5.2.5 Install Manifests Copy Files Next to Your Application

The *FileManifest* Starlark type represents a collection of files and their content. When FileManifest instances are returned from a target function, their build action results in their contents being manifested in a directory having the name of the build target.

FileManifest instances can be used to construct custom file install layouts.

Say you have an existing directory tree of files you want to copy next to your built executable defined by the PythonExecutable type.

The *glob()* function can be used to discover existing files on the filesystem and turn them into a FileManifest. You can then return this FileManifest directory or overlay it onto another instance using *FileManifest.add\_manifest()*. Here's an example:

```
def make_dist():
    return default_python_distribution()

def make_exe(dist):
    return dist.to_python_executable("myapp")

def make_install(exe):
    m = FileManifest()

    m.add_python_resource(".", exe)

    templates = glob("/path/to/project/templates/**/*", strip_prefix="/path/to/
    →project/")
    m.add_manifest(templates)
    return m

register_target("dist", make_dist)
register_target("exe", make_exe, depends=["dist"])
register_target("install", make_install, depends=["exe"], default=True)
```

We introduce a new install target and make\_install() function which returns a FileManifest. It adds the PythonExecutable (represented by the exe argument/variable) to that manifest in the root directory, signified by ...

Next, it calls glob() to find all files in the /path/to/project/templates/ directory tree, strips the path prefix /path/to/project/ from them, and then merges all of these files into the final manifest.

When the InstallManifest is built, the final layout should look something like the following:

- install/myapp (or install/myapp.exe on Windows)
- install/templates/foo
- install/templates/...

See Packaging Files Instead of In-Memory Resources for more on this topic.

## 5.3 Understanding Python Distributions

The *PythonDistribution* Starlark type represents a Python *distribution*, an entity providing a Python installation and build files which PyOxidizer uses to build your applications. See *Python Distributions Provide Python* for more.

## 5.3.1 Available Python Distributions

PyOxidizer ships with its own list of available Python distributions. These are constructed via the *de-fault\_python\_distribution()* Starlark method. Under most circumstances, you'll want to use one of these distributions instead of providing your own because these distributions are tested and should have maximum compatibility.

Source	Version	Flavor	Build Target
CPython	3.8.6	standalone_dynamic	x86_64-unknown-linux-gnu
CPython	3.9.0	standalone_dynamic	x86_64-unknown-linux-gnu
CPython	3.8.6	standalone_static	x86_64-unknown-linux-musl
CPython	3.9.0	standalone_static	x86_64-unknown-linux-musl
CPython	3.8.6	standalone_dynamic	i686-pc-windows-msvc
CPython	3.9.0	standalone_dynamic	i686-pc-windows-msvc
CPython	3.8.6	standalone_static	i686-pc-windows-msvc
CPython	3.9.0	standalone_static	i686-pc-windows-msvc
CPython	3.8.6	standalone_dynamic	x86_64-pc-windows-msvc
CPython	3.9.0	standalone_dynamic	x86_64-pc-windows-msvc
CPython	3.8.6	standalone_static	x86_64-pc-windows-msvc
CPython	3.9.0	standalone_static	x86_64-pc-windows-msvc
CPython	3.8.6	standalone_dynamic	x86_64-apple-darwin
CPython	3.9.0	standalone_dynamic	x86_64-apple-darwin

Here are the built-in Python distributions:

All of these distributions are provided by the python-build-standalone, and are maintained by the maintainer of PyOx-idizer.

## 5.3.2 Python Version Compatibility

PyOxidizer is capable of working with Python 3.8 and 3.9.

Python 3.8 is the default Python version because it has been around for a while and is relatively stable. Once Python 3.9 matures, it will eventually become the default Python version.

PyOxidizer's tests are run primarily against the default Python version. So adopting a non-default version may risk running into subtle bugs.

## 5.3.3 Choosing a Python Distribution

The Python 3.8 distributions are the default and are better tested than the Python 3.9 distributions. If you care about stability, you should use 3.8.

The standalone\_dynamic distributions behave much more similarly to traditional Python build configurations than do their standalone\_static counterparts. The standalone\_dynamic distributions are capable of load-ing Python extension modules that exist as shared library files. So when working with standalone\_dynamic distributions, Python wheels containing pre-built Python extension modules often *just work*.

The downside to standalone\_dynamic distributions is that you cannot produce a single file, statically-linked executable containing your application in most circumstances: you will need a standalone\_static distribution to produce a single file executable.

But as soon as you encounter a third party extension module with a standalone\_static distribution, you will need to recompile it. And this is often unreliable.

## 5.3.4 Binary Portability of Distributions

The built-in Python distributions are built in such a way that they should run on nearly every system for the platform they target. This means:

- All 3rd party shared libraries are part of the distribution (e.g. libssl and libsqlite3) and don't need to be provided by the run-time environment.
- Some distributions are statically linked and have no dependencies on any external shared libraries.
- On the glibc linked Linux distributions, they use an old glibc version for symbol versions, enabling them to run on Linux distributions created years ago. (The current version is 2.19, which was released in 2014.)
- Any shared libraries not provided by the distribution are available in base operating system installs. On Linux, example shared libraries include libc.so.6 and linux-vdso.so.1, which are part of the Linux Standard Base Core Configuration and should be present on all conforming Linux distros. On macOS, referenced dylibs include libSystem, which is part of the macOS core install.
- On macOS, distributions are compiled with MACOSX\_DEPLOYMENT\_TARGET=10.9 so they only used SDK features present on macOS >=10.9, enabling them to run on sufficiently old macOS versions.

## 5.4 Managing How Resources are Added

An important concept in PyOxidizer packaging is how to manage resources that are added to built applications.

A *resource* is some entity that will be packaged and distributed. Examples of *resources* include Python module source and bytecode, Python extension modules, and arbitrary files on the filesystem.

Resources are represented by a dedicated Starlark type for each resource flavor (see Resource Types).

During evaluation of PyOxidizer's Starlark configuration files, *resources* are created and *added* to another Starlark type whose job is to collect all desired *resources* and then do something with them.

## 5.4.1 Classified Resources Versus Files

All resources in PyOxidizer are ultimately derived from or representable by a file or a file-like primitive. For example, a *PythonModuleSource* is derived from or could be manifested as a .py file.

Various PyOxidizer functionality works by scanning existing files and turning those files into resources.

This file scanning functionality has two modes of operation: *classified* and *files*. In *files* mode, PyOxidizer simply emits resources corresponding to the raw files it encounters. In *classified* mode, PyOxidizer attempts to *classify* a file as a particular resource and emit a strongly-typed resource like *PythonModuleSource* or *PythonExtensionModule*.

*Classified* mode is more powerful because PyOxidizer is able to build an *index* of typed resources at packaging time and make this *index* available to *oxidized\_importer Python Extension* at run-time to facilitate faster loading of resources.

However, the main downside to *classified* mode is it relies on being able to identify files properly and this is unreliable. Python file layouts are under-specified and there are many edge cases where PyOxidizer fails to properly classify a file. See *Debugging Resource Scanning and Identification with find-resources* for how to identify problems here.

In *files* mode, PyOxidizer simply indexes and manages a named file and its content. There is far less potential for PyOxidizer to make mistakes about a file's type and how it is handled. This means that *files* mode often *just works* when *classified* mode doesn't. The main downside to *files* mode is that *oxidized\_importer Python Extension* doesn't have a rich index embedded in the built binary, so you will have to rely on Python's default filesystem-based importer, which is slower than oxidized\_importer.

## 5.4.2 Packaging Policies and Adding Resources

The exact mechanism by which *resources* are emitted and added to *resource collectors* is influenced by a *packaging policy* (represented by the *PythonPackagingPolicy* Starlark type) and attributes on each resource object influencing how they are added.

When *resources* are created, the *packaging policy* determines whether emitted resources are *classified* or simply *files*. And the *packaging policy* is applied to each created resource to populate the initial values for the various add\_\* attributes on the Starlark *resource* types.

When a resource is added (e.g. by calling PythonExecutable.add\_python\_resource()), these aforementioned add\_\* attributes are consulted and used to influence exactly how that *resource* is added/packaged.

For example, a *PythonModuleSource* can set attributes indicating to exclude source code and only generate bytecode at a specific optimization level. Or a *PythonExtensionModule* can set attributes saying to prefer to compile it into the built binary or materialize it as a standalone dynamic extension module (e.g. my\_ext.so or my\_ext.pyd).

## 5.4.3 Resource Types

The following Starlark types represent individual resources:

PythonModuleSource Source code for a Python module. Roughly equivalent to a .py file.

This type can also be converted to Python bytecode (roughly equivalent to a .pyc) when added to a resource collector.

- *PythonExtensionModule* A Python module defined through compiled, machine-native code. On Linux, these are typically encountered as . so files. On Windows, .pyd files.
- *PythonPackageResource* A non-module *resource file* loadable by Python resources APIs, such as those in importlib.resources.
- *PythonPackageDistributionResource* A non-module *resource file* defining metadata for a Python package. Typically accessed via importlib.metadata. This is how files in \*.dist-info or \*.egg-info directories are represented.
- File Represents a filesystem path and its content.
- *FileContent* Represents the content of a filesystem file.

This is different from *File* in that it only represents file content and doesn't have an associated path. (It is likely these 2 types will be merged someday.)

There are also Starlark types that are logically containers for multiple resources:

- *FileManifest* Holds a mapping of relative filesystem paths to FileContent instances. This type effectively allows modeling a directory tree.
- *PythonEmbeddedResources* Holds a collection of Python resources of various types. (This type is often hidden away. e.g. inside a PythonExecutable instance.)

## 5.4.4 Resource Locations

Resources have the concept of a *location*. A resource's *location* determines where the data for that resource is packaged and how that resource is loaded at run-time.

### **In-Memory**

When a Python resource is placed in the *in-memory* location, the content behind the resource will be embedded in a built binary and loaded from there by the Python interpreter.

Python modules imported from memory do not have the \_\_\_file\_\_\_ attribute set. This can cause compatibility issues if Python code is relying on the existence of this module. See \_\_*file\_\_* and \_\_*cached\_\_* Module Attributes for more.

### **Filesystem-Relative**

When a Python resource is placed in the *filesystem-relative* location, the resource will be materialized as a file next to the produced entity. e.g. a *filesystem-relative* PythonModuleSource for the foo.bar Python module added to a PythonExecutable will be materialized as the file foo/bar.py or foo/bar/\_\_init\_\_.py in a directory next to the built executable.

Resources added to *filesystem-relative* locations should be materialized under paths that preserve semantics with standard Python file layouts. For e.g. Python source and bytecode modules, it should be possible to point sys.path of any Python interpreter at the destination directory and the modules will be loadable.

During packaging, PyOxidizer *indexes* all *filesystem-relative* resources and embeds metadata about them in the built binary. While the files on the filesystem may look like a standard Python install layout, loading them is serviced by PyOxidizer's custom importer, not the standard importer that Python uses by default.

## 5.4.5 Customizing Python Packaging Policies

As described in *Packaging Policies and Adding Resources*, a PythonPackagingPolicy Starlark type instance is bound to every entity creating *resource* instances and this *packaging policy* is used to derive the default add\_\* attributes which influence what happens when a resource is added to some entity.

PythonPackagingPolicy instances can be customized to influence what the default values of the add\_\* attributes are.

The primary mechanisms for doing this are:

- 1. Modifying the PythonPackagingPolicy instance's internal state. See *PythonPackagingPolicy* for the full list of object attributes and methods that can be set or called.
- 2. Registering a function that will be called whenever a resource is created. This enables custom Starlark code to perform arbitrarily complex logic to influence settings and enables application developers to devise packaging strategies more advanced than what PyOxidizer provides out-of-the-box.

The following sections give examples of customized packaging policies.

## **Changing the Resource Handling Mode**

As documented in *Classified Resources Versus Files*, PyOxidizer can operate on *classified* resources or *files*-based resources.

*PythonPackagingPolicy.set\_resource\_handling\_mode()* exists to change the operating mode of a PythonPackagingPolicy instance.

```
def make_exe():
    dist = default_python_distribution()
    policy = dist.make_python_packaging_policy()
```

(continues on next page)

(continued from previous page)

```
# Set policy attributes to only operate on "classified" resource types.
# (This is the default.)
policy.set_resource_handling_mode("classify")
# Set policy attributes to only operate on `File` resource types.
policy.set_resource_handling_mode("files")
```

*PythonPackagingPolicy.set\_resource\_handling\_mode()* is just a convenience method for manipulating a collection of attributes on PythonPackagingPolicy instances. If you don't like the behavior of its pre-defined modes, feel free to adjust attributes to suit your needs. You can even configure things to emit both *classified* and *files* variants simultaneously!

### **Customizing Default Resource Locations**

The PythonPackagingPolicy.resources\_location and PythonPackagingPolicy.resources\_location\_fallback attributes define primary and fallback locations that resources should attempt to be added to. These effectively define the default values for the add\_location and add\_location\_fallback attributes on individual resource objects.

The accepted values are:

in-memory Load resources from memory.

filesystem-relative:prefix Load resources from the filesystem at a path relative to some entity (probably the binary being built).

Additionally, PythonPackagingPolicy.resources\_location\_fallback can be set to None to remove a fallback location.

And here is how you would manage these values in Starlark:

```
def make_exe():
   dist = default_python_distribution()
   policy = dist.make_python_packaging_policy()
   policy.resources_location = "in-memory"
   policy.resources_location_fallback = None
   # Only allow resources to be added to the in-memory location.
   exe = dist.to_python_executable(
       name = "myapp",
       packaging_policy = policy,
   )
    # Only allow resources to be added to the filesystem-relative location under
    # a "lib" directory.
   policy = dist.make_python_packaging_policy()
   policy.resources_location = "filesystem-relative:lib"
   policy.resources_location_fallback = None
   exe = dist.to_python_executable(
       name = "myapp",
       packaging_policy = policy,
   )
    # Try to add resources to in-memory first. If that fails, add them to a
```

(continues on next page)

(continued from previous page)

```
# "lib" directory relative to the built executable.
policy = dist.make_python_packaging_policy()
policy.resources_location = "in-memory"
policy.resources_location_fallback = "filesystem-relative:lib"
exe = dist.to_python_executable(
    name = "myapp",
    packaging_policy = policy,
)
return exe
```

## Using Callbacks to Influence Resource Attributes

The PythonPackagingPolicy.register\_resource\_callback(func) method will register a function to be called when resources are created. This function receives as arguments the active PythonPackagingPolicy and the newly created resource.

Functions registered as resource callbacks are called after the add\_\* attributes are derived for a resource but before the resource is otherwise made available to other Starlark code. This means that these callbacks provide a hook point where resources can be modified as soon as they are created.

register\_resource\_callback() can be called multiple times to register multiple callbacks. Registered functions will be called in order of registration.

Functions can be leveraged to unify all resource packaging logic in a single place, making your Starlark configuration files easier to reason about.

Here's an example showing how to route all resources belonging to a single package to a filesystem-relative location and everything else to memory:

```
def resource_callback(policy, resource):
   if type(resource) in ("PythonModuleSource", "PythonPackageResource",
→ "PythonPackageDistributionResource"):
        if resource.package == "my_package":
            resource.add_location = "filesystem-relative:lib"
        else:
            resource.add_location = "in-memory"
def make_exe():
   dist = default_python_distribution()
   policy = dist.make_python_packaging_policy()
   policy.register_resource_callback(resource_callback)
   exe = dist.to_python_executable(
       name = "myapp",
        packaging_policy = policy,
    )
    exe.add_python_resources(exe.pip_install(["my_package"]))
```

## 5.4.6 PythonExtensionModule Location Compatibility

Many resources just work in any available location. This is not the case for PythonExtensionModule instances!

While there only exists a single PythonExtensionModule type to represent Python extension modules, Python extension modules come in various flavors. Examples of flavors include:

- A module that is part of a Python *distribution* and is compiled into libpython (a *builtin* extension module).
- A module that is part of a Python *distribution* that is compiled as a standalone shared library (e.g. a .so or .pyd file).
- A non-distribution module that is compiled as a standalone shared library.
- A non-*distribution* module that is compiled as a static library.

Not all extension module *flavors* are compatible with all Python *distributions*. Furthermore, not all *flavors* are compatible with all build configurations.

Here are some of the rules governing extension modules and their locations:

- A builtin extension module that's part of a Python distribution will always be statically linked into libpython.
- A Windows Python distribution with a statically linked libpython (e.g. the standalone\_static *distribution flavor*) is not capable of loading extension modules defined as shared libraries and only supports loading *builtin* extension modules statically linked into the binary.
- A Windows Python distribution with a dynamically linked libpython (e.g. the standalone\_dynamic *distribution flavor*) is capable of loading shared library backed extension modules from the *in-memory* location. Other operating systems do not support the *in-memory* location for loading shared library extension modules.
- If the current build configuration targets Linux MUSL-libc, shared library extension modules are not supported and all extensions must be statically linked into the binary.
- If the object files for the extension module are available, the extension module may be statically linked into the produced binary.
- If loading extension modules from in-memory import is supported, the extension module will have its dynamic library embedded in the binary.
- The extension module will be materialized as a file next to the produced binary and will be loaded from the filesystem. (This is how Python extension modules typically work.)

**Note:** Extension module handling is one of the more nuanced aspects of PyOxidizer. There are likely many subtle bugs and room for improvement. If you experience problems handling extension modules, please consider filing an issue.

## 5.5 Packaging Python Files

The most important packaged *resource type* are arguably Python files: source modules, bytecode modules, extension modules, package resources, etc.

For PyOxidizer to recognize these Python resources as Python resources (as opposed to regular files), you will need to use the methods on the *PythonExecutable* Starlark type to use the settings from the thing being built to scan for resources, possibly performing a Python packaging action (such as invoking pip install) along the way.

This documentation covers the available methods and how they can be used.

## 5.5.1 PythonExecutable Python Resources Methods

The PythonExecutable Starlark type has the following methods that can be called to perform an action and obtain an iterable of objects representing discovered resources:

pip\_download(...) Invokes pip download with specified arguments and collects resources discovered from downloaded Python wheels.

*pip\_install(...)* Invokes pip install with specified arguments and collects all resources installed by that process.

- read\_package\_root(...) Recursively scans a filesystem directory for Python resources in a typical Python installation
  layout.
- setup\_py\_install(...) Invokes python setup.py install for a given path and collects resources installed by
  that process.

*read\_virtualenv(...)* Reads Python resources present in an already populated virtualenv.

Typically, the Starlark types resolved by these method calls are passed into a method that adds the resource to a to-be-generated entity, such as the *PythonExecutable* Starlark type.

The following sections demonstrate common use cases.

## 5.5.2 Packaging an Application from a PyPI Package

In this section, we'll show how to package the pyflakes program using a published PyPI package. (Pyflakes is a Python linter.)

First, let's create an empty project:

```
$ pyoxidizer init-config-file pyflakes
```

Next, we need to edit the *configuration file* to tell PyOxidizer about pyflakes. Open the pyflakes/pyoxidizer. bzl file in your favorite editor.

Find the make\_exe() function. This function returns a *PythonExecutable* instance which defines a standalone executable containing Python. This function is a registered *target*, which is a named entity that can be individually built or run. By returning a PythonExecutable instance, this function/target is saying *build an executable containing Python*.

The PythonExecutable type holds all state needed to package and run a Python interpreter. This includes lowlevel interpreter configuration settings to which Python resources (like source and bytecode modules) are embedded in that executable binary. This type exposes an *add\_python\_resources()* method which adds an iterable of objects representing Python resources to the set of embedded resources.

Elsewhere in this function, the dist variable holds an instance of *PythonDistribution*. This type represents a Python distribution, which is a fancy way of saying *an implementation of Python*.

Two of the methods exposed by PythonExecutable are *pip\_download()* and *pip\_install()*, which invoke pip commands with settings to target the built executable.

To add a new Python package to our executable, we call one of these methods then add t he results to our PythonExecutable instance. This is done like so:

```
exe.add_python_resources(exe.pip_download(["pyflakes==2.2.0"]))
# or
exe.add_python_resources(exe.pip_install(["pyflakes==2.2.0"]))
```

When called, these methods will effectively run pip download pyflakes==2.2.0 or pip install pyflakes==2.2.0, respectively. Actions are performed in a temporary directory and after pip runs, PyOxidizer will collect all the downloaded/installed resources (like module sources and bytecode data) and return them as an iterable of Starlark values. The exe.add\_python\_resources() call will then teach the built executable binary about the existence of these resources. Many resource types will be embedded in the binary and loaded from binary. But some resource types (notably compiled extension modules) may be installed next to the built binary and loaded from the filesystem.

Next, we tell PyOxidizer to run pyflakes when the interpreter is executed:

python\_config.run\_mode = "eval:from pyflakes.api import main; main()"

This says to effectively run the Python code eval(from pyflakes.api import main; main()) when the embedded interpreter starts.

The new make\_exe() function should look something like the following (with comments removed for brevity):

```
def make_exe():
   dist = default_python_distribution()
   policy = dist.make_python_packaging_policy()
   policy.extension_module_filter = "all"
   policy.include_distribution_sources = True
   policy.include_distribution_resources = True
   policy.include_test = False
   config = dist.make_python_interpreter_config()
   config.run_mode = "eval:from pyflakes.api import main; main()"
   exe = dist.to_python_executable(
       name="pyflakes",
       packaging_policy=policy,
       config=config,
   )
   exe.add_python_resources(exe.pip_install(["pyflakes==2.1.1"]))
   return exe
```

With the configuration changes made, we can build and run a pyflakes native executable:

```
# From outside the ``pyflakes`` directory
$ pyoxidizer run --path /path/to/pyflakes/project -- /path/to/python/file/to/analyze
# From inside the ``pyflakes`` directory
$ pyoxidizer run -- /path/to/python/file/to/analyze
# Or if you prefer the Rust native tools
$ cargo run -- /path/to/python/file/to/analyze
```

By default, pyflakes analyzes Python source code passed to it via stdin.

## 5.5.3 Packaging an Application from an Existing Virtualenv

This scenario is very similar to the above example. So we'll only briefly describe what to do so we don't repeat ourselves.:

\$ pyoxidizer init-config-file /path/to/myapp

Now edit the pyoxidizer.bzl so the make\_exe() function look like the following:

```
def make_exe():
   dist = default_python_distribution()
   policy = dist.make_python_packaging_policy()
   policy.extension_module_filter = "all"
   policy.include_distribution_sources = True
   policy.include_distribution_resources = False
   policy.include_test = False
   config = dist.make_python_interpreter_config()
   config.run_mode = "eval:from myapp import main; main()"
   exe = dist.to_python_executable(
       name="myapp",
       packaging_policy=policy,
       config=config,
   )
   exe.add_python_resources(exe.read_virtualenv("/path/to/virtualenv"))
   return exe
```

Of course, you need a populated virtualenv!:

\$ python3.8 -m venv /path/to/virtualenv \$ /path/to/virtualenv/bin/pip install -r /path/to/requirements.txt

Once all the pieces are in place, simply run pyoxidizer to build and run the application:

\$ pyoxidizer run --path /path/to/myapp

**Warning:** When consuming a pre-populated virtualenv, there may be compatibility differences between the Python distribution used to populate the virtualenv and the Python distributed used by PyOxidizer at build and application run time.

For best results, it is recommended to use a packaging method like pip\_install(...) or setup\_py\_install(...) to use PyOxidizer's Python distribution to invoke Python's packaging tools.

## 5.5.4 Packaging an Application from a Local Python Package

Say you have a Python package/application in a local directory. It follows the typical Python package layout and has a setup.py file and Python files in sub-directories corresponding to the package name. e.g.:

```
setup.py
mypackage/__init__.py
mypackage/foo.py
```

You have a number of choices as to how to proceed here. Again, the workflow is very similar to what was explained above. The main difference is the content of the pyoxidizer.bzl file and the exact *method* to call to obtain the Python resources.

You could use pip install <local path> to use pip to process a local filesystem path:

exe.add\_python\_resources(exe.pip\_install(["/path/to/local/package"]))

If the pyoxidizer.bzl file is in the same directory as the directory you want to process, you can derive the absolute path to this directory via the *CWD* Starlark variable:

exe.add\_python\_resources(exe.pip\_install([CWD]))

If you don't want to use pip and want to run setup.py directly, you can do so:

exe.add\_python\_resources(exe.setup\_py\_install(package\_path=CWD))

Or if you don't want to run a Python packaging tool at all and just scan a directory tree for Python files:

exe.add\_python\_resources(exe.read\_package\_root(CWD, ["mypackage"]))

**Note:** In this mode, all Python resources must already be in place in their final installation layout for things to work correctly. Many setup.py files perform additional actions such as compiling Python extension modules, installing additional files, dynamically generating some files, or changing the final installation layout.

For best results, use a packaging method that invokes a Python packaging tool (like pip\_install(...) or setup\_py\_install(...).

## 5.5.5 Choosing Which Packaging Method to Call

There are a handful of different methods for obtaining Python resources that can be added to a resource collection. Which one should you use?

The reason there are so many methods is because the answer is: *it depends*.

Each method for obtaining resources has its niche use cases. That being said, the preferred method for obtaining Python resources is pip\_download(). However, pip\_download() may not work in all cases, which is why other methods exist.

*PythonExecutable.pip\_download()* runs pip download and attempts to fetch Python wheels for specified packages, requirements files, etc. It then extracts files from inside the wheel and converts them to Python resources which can be added to resource collectors.

**Important:** pip\_download() will only work if a compatible Python *wheel* package (.whl file) is available. If the configured Python package repository doesn't offer a compatible wheel for the specified package or any of its dependencies, the operation will fail.

Many Python packages do not yet publish wheels (only .tar.gz archives) or don't publish at all to Python package repositories (this is common in corporate environments, where you don't want to publish your proprietary packages on PyPI or you don't run a Python package server).

**Important:** Not all build targets support pip\_download() for all published packages. For example, when targeting Linux musl libc, built binaries are fully static and aren't capable of loading Python extension modules (which are shared libraries). So pip\_download() only supports source-only Python wheels in this configuration. Another advantage of pip\_download() is it supports cross-compiling. Unlike pip install, pip download supports arguments that tell it which Python version, platform, implementation, etc to download packages for. PyOx-idizer automatically tells pip download to download wheels that are compatible with the target environment you are building for. This means you can do things like download wheels containing Windows binaries when building on Linux.

**Note:** Cross-compiling is not yet fully supported by PyOxidizer and likely doesn't work in many cases. However, this is a planned feature (at least for some configurations) and pip\_download() is likely the most future-proof mechanism to support installing Python packages when cross-compiling.

A potential downside with pip\_download() is that it only supports classical Python binary loading/shipping techniques. If you are trying to produce a statically linked executable containing custom Python extension modules, pip\_download() won't work for you.

After pip\_download, *PythonExecutable.pip\_install()* and *PythonExecutable.setup\_py\_install()* are the next most-preferred packaging methods.

Both of these work by locally running a Python packaging action (pip install or python setup.py install, respectively) and then collecting resources installed by that action.

The advantage over pip download is that a pre-built Python wheel does not have to be available and published on a Python package repository for these commands to work: you can run either against say a local version control checkout of a Python project and it should work.

The main disadvantage over pip download is that you are running Python packaging operations on the local machine as part of building an executable. If your package contains just Python code, this should *just work*. But if you need to compile extension modules, there's a good chance your local machine may either not be able to build them properly or will build those extension modules in such a way that they aren't compatible with other machines you want to run them on.

The final options for obtaining Python resources are *PythonExecutable.read\_package\_root()* and *PythonExecutable.read\_virtualenv()*. Both of these methods rely on traversing a filesystem tree that is already populated with Python resources. This should *just work* if only pure Python resources are in play. But if there are compiled Python extension modules, all bets are off and there is no guarantee that found extension modules will be compatible with PyOxidizer or will have binary compatibility with other machines. These resource discovery mechanisms also rely on state not under the control of PyOxidizer and therefore packaging results may be highly inconsistent and not reproducible across runs. For these reasons, read\_package\_root() and read\_virtualenv() are the least preferred methods for Python resource discovery.

## 5.6 Packaging Files Instead of In-Memory Resources

By default, PyOxidizer will *classify* files into typed resources and attempt to load these resources from memory (with the exception of compiled extension modules, which require special treatment). Please read *Managing How Resources are Added*, specifically *Classified Resources Versus Files* and *Resource Locations* for more on the concepts of *classification* and *resource locations*.

This is the ideal packaging method because it keeps the entire application self-contained and can result in *performance wins* at run-time.

However, sometimes this approach isn't desired or flat out doesn't work. Fear not: PyOxidizer has you covered.

## 5.6.1 Examples of Packaging Failures

Let's give some concrete examples of how PyOxidizer's default packaging settings can fail.

#### black

Let's demonstrate a failure attempting to package black, a Python code formatter.

We start by creating a new project:

```
$ pyoxidizer init-config-file black
```

Then edit the pyoxidizer.bzl file to have the following:

```
def make_exe(dist):
    config = dist.make_python_interpreter_config()
    config.run_mode = "module:black"
    exe = dist.to_python_executable(
        name = "black",
    )
    for resource in exe.pip_install(["black==19.3b0"]):
        resource.add_location = "in-memory"
        exe.add_python_resource(resource)
    return exe
```

Iecuin exe

Then let's attempt to build the application:

```
$ pyoxidizer build --path black
processing config file /home/gps/src/black/pyoxidizer.bzl
resolving Python distribution...
...
```

#### Looking good so far!

#### Now let's try to run it:

```
$ pyoxidizer run --path black
Traceback (most recent call last):
  File "black", line 46, in <module>
  File "blib2to3.pygram", line 15, in <module>
NameError: name '___file__' is not defined
SystemError
```

Uh oh - that's didn't work as expected.

As the error message shows, the blib2to3.pygram module is trying to access \_\_file\_\_, which is not defined. As explained by \_\_*file\_\_ and \_\_cached\_\_ Module Attributes*, PyOxidizer doesn't set \_\_file\_\_ for modules loaded from memory. This is perfectly legal as Python doesn't mandate that \_\_file\_\_ be defined. But black (and many other Python modules) assume \_\_file\_\_ always exists. So it is a problem we have to deal with.

#### **NumPy**

Let's attempt to package NumPy, a popular Python package used by the scientific computing crowd.

\$ pyoxidizer init-config-file numpy

Then edit the pyoxidizer.bzl file to have the following:

```
def make_exe(dist):
    policy = dist.make_python_packaging_policy()
    policy.resources_location_fallback = "filesystem-relative:lib"
    exe = dist.to_python_executable(
        name = "numpy",
        packaging_policy = policy,
    )
    for resource in exe.pip_download(["numpy==1.19.0"]):
        resource.add_location = "filesystem-relative:lib"
        exe.add_python_resource(resource)
    return exe
```

We did things a little differently from the black example above: we're explicitly adding NumPy's resources into the filesystem-relative location so they are materialized as files instead of loaded from memory. This is to demonstrate a separate failure mode.

Then let's attempt to build the application:

```
$ pyoxidizer build --path numpy
processing config file /home/gps/src/numpy/pyoxidizer.bzl
resolving Python distribution...
...
```

#### Looking good so far!

Now let's try to run it:

```
$ pyoxidizer run --path numpy
...
Python 3.8.6 (default, Oct 3 2020, 20:48:20)
[Clang 10.0.1 ] on linux
Type "help", "copyright", "credits" or "license" for more information.
>>> import numpy
Traceback (most recent call last):
   File "numpy.core", line 22, in <module>
   File "numpy.core.multiarray", line 12, in <module>
   File "numpy.core.overrides", line 7, in <module>
   ImportError: libopenblasp-r0-ae94cfde.3.9.dev.so: cannot open shared object file: No_
        →such file or directory
During handling of the above exception, another exception occurred:
...
```

#### That's not good! What happened?

Well, the hint is in the stack trace: libopenblasp-r0-ae94cfde.3.9.dev.so: cannot open shared object file: No such file or directory. So there's a file named libopenblasp-r0-ae94cfde.3.9.dev.so that can't be found. Let's look in our install layout:

(continued from previous page)

Well, we found some files, including a . so file! But the filename has been mangled.

This filename mangling is actually a bug in PyOxidizer's file/resource classification. See Incorrect Resource Identification and Classified Resources Versus Files for more.

#### 5.6.2 Installing Classified Resources on the Filesystem

In the *black* example above, we saw how black failed to run with modules imported from memory because of \_\_\_\_\_\_file\_\_\_ not being defined.

In scenarios where in-memory resource loading doesn't work, the ideal mitigation is to fix the offending Python modules so they can load from memory. But this isn't always trivial or possible with 3rd party dependencies.

Your next mitigation should be to attempt to place the resource on the filesystem, next to the built binary.

This will require configuration file changes.

The goal of our new configuration is to materialize Python resources associated with black on the filesystem instead of in memory.

Change your configuration file so make\_exe() looks like the following:

```
def make_exe(dist):
    policy = dist.make_python_packaging_policy()
    policy.resources_location_fallback = "filesystem-relative:lib"
    python_config = dist.make_python_interpreter_config()
    python_config.run_mode = "module:black"
    exe = dist.to_python_executable(
        name = "black",
        packaging_policy = policy,
        config = python_config,
    )
    for resource in exe.pip_install(["black==19.3b0"]):
        resource.add_location = "filesystem-relative:lib"
        exe.add_python_resource(resource)
```

There are a few changes here.

We constructed a new *PythonPackagingPolicy* via *PythonDistribution.make\_python\_packaging\_policy()* and set its *resources\_location\_fallback* attribute to filesystem-relative-lib. This allows us to install resources on the filesystem, relative to the produced binary.

Next, in the for resource in exe.pip\_install(...) loop, we set resource.add\_location = "filesystem-relative:lib". What this does is tell the subsequent call to *PythonExe-cutable.add\_python\_resource()* to add the resource as a filesystem-relative resource in the lib directory.

With the new configuration in place, let's re-build and run the application:

```
$ pyoxidizer run --path black
...
adding extra file lib/toml-0.10.1.dist-info/top_level.txt to .
installing files to /home/gps/tmp/myapp/build/x86_64-unknown-linux-gnu/debug/install
No paths given. Nothing to do
```

That No paths given output is from black: it looks like the new configuration worked!

If you examine the build output, you'll see a bunch of messages indicating that extra files are being installed to the lib/ directory. And if you poke around in the install directory, you will in fact see all these files.

In this configuration file, the Python distribution's files are all loaded from memory but black resources (collected via pip install black) are materialized on the filesystem. All of the resources are indexed by PyOxidizer at build time and that index is embedded into the built binary so *oxidized\_importer Python Extension* can find and load resources more efficiently.

Because only some of the Python modules used by black have a dependency on \_\_file\_\_, it is probably possible to cherry pick exactly which resources are materialized on the filesystem and minimize the number of files present. We'll leave that as an exercise for the reader.

### 5.6.3 Installing Unclassified Files on the Filesystem

In *Installing Classified Resources on the Filesystem* we demonstrated how to move *classified* resources from memory to the filesystem in order to work around issues importing a module from memory.

Astute readers may have already realized that this workaround (setting .add\_location to filesystem-relative:...) was attempted in the *NumPy* failure example above. So this workaround doesn't always work.

In cases where PyOxidizer's resource classifier or logic to materialize those classified resources as files is failing (presumably due to bugs in PyOxidizer), you can fall back to using *unclassified*, file-based resources. See *Classified Resources Versus Files* for more on *classified* versus *files* based resources.

Our approach here is to switch from *classified* to *files* packaging mode. Using our NumPy example from above, change the make\_exe() in your configuration file to as follows:

```
def make_exe(dist):
    policy = dist.make_python_packaging_policy()
    policy.set_resource_handling_mode("files")
    policy.resources_location_fallback = "filesystem-relative:lib"
    python_config = dist.make_python_interpreter_config()
    python_config.module_search_paths = ["$ORIGIN/lib"]
    exe = dist.to_python_executable(
        name = "numpy",
        packaging_policy = policy,
        config = python_config,
    )
    for resource in exe.pip_download(["numpy==1.19.0"]):
        resource.add_location = "filesystem-relative:lib"
        exe.add_python_resource(resource)
    return exe
```

There are a few key lines here.

policy.set\_resource\_handling\_mode("files") calls a method on the *PythonPackagingPolicy* to set the resource handling mode to *files*. This effectively enables *File* based resources to work. Without it, resource scanners won't emit *File* and attempts at adding *File* to a resource collection will fail.

Next, we enable file-based resource installs by setting *resources\_location\_fallback*.

Another new line is python\_config.module\_search\_paths = ["\$ORIGIN/lib"]. This all-important line to set *module\_search\_paths* effectively installs the lib directory next to the executable on sys.path at runtime. And as a side-effect of defining this attribute, Python's built-in module importer is enabled (to supplement oxidized\_importer). This is important because because when you are operating in *files* mode, resources are indexed as *files* and not classified/typed resources. This means oxidized\_importer doesn't recognize them as loadable Python modules. But since you enable Python's standard importer and register lib/ as a search path, Python's standard importer will be able to find the numpy package at run-time.

Anyway, let's see if this actually works:

```
$ pyoxidizer run --path numpy
...
adding extra file lib/numpy.libs/libgfortran-2e0d59d6.so.5.0.0 to .
adding extra file lib/numpy.libs/libopenblasp-r0-ae94cfde.3.9.dev.so to .
adding extra file lib/numpy.libs/libu-eb09ad1d.so.1.2.3 to .
adding extra file lib/numpy.libs/libu-eb09ad1d.so.1.2.3 to .
installing files to /home/gps/tmp/myapp/build/x86_64-unknown-linux-gnu/debug/install
Python 3.8.6 (default, Oct 3 2020, 20:48:20)
[Clang 10.0.1 ] on linux
Type "help", "copyright", "credits" or "license" for more information.
>>> import numpy
>>> numpy.__loader___
<_frozen_importlib_external.SourceFileLoader object at 0x7f063da1c7f0>
```

#### It works!

Critically, we see that the formerly missing libopenblasp-r0-ae94cfde.3.9.dev.so file is being installed to the correct location. And we can confirm from the numpy.\_\_loader\_\_ value that the standard library's module loader is being used. Contrast with a standard library module:

```
>>> import pathlib
>>> pathlib.__loader___
<OxidizedFinder object at 0x7f063dc8f8f0>
```

Enabling *files* mode and falling back to Python's importer is often a good way of working around bugs in PyOxidizer's *resource handling*. But it isn't bulletproof.

**Important:** Please *file a bug report <https://github.com/indygreg/PyOxidizer/issues>* if you encounter any issues with PyOxidizer's handling of resources and paths.

# 5.7 Working with Python Extension Modules

Python extension modules are machine native code exposing functionality to a Python interpreter via Python modules.

PyOxidizer has varying levels of support for extension modules. This is because some PyOxidizer configurations break assumptions about how Python interpreters typically run.

This document attempts to capture all the nuances of working with Python extension modules with PyOxidizer.

### 5.7.1 Extension Module Flavors

Python extension modules exist as either *built-in* or *standalone*. A *built-in* extension module is statically linked into *libpython* and a *standalone* extension module is a shared library that is dynamically loaded at run-time.

Typically, *built-in* extension modules only exist in Python distributions (and are part of the Python standard library by definition) and Python package maintainers only ever produce *standalone* extension modules (e.g. as .so or .pyd files).

Python distributions typically contain a mix of *built-in* and *standalone* extension modules. e.g. the \_ast extension module is *built-in* and the \_ssl extension module is *standalone*.

**Important:** Because PyOxidizer enables you to build your own binaries embedding Python and because different Python distributions have different levels of support for extension modules, it is important to familiarize yourself with the types of extension modules and how they can be used.

### 5.7.2 Extension Module Restrictions

PyOxidizer imposes a handful of restrictions on how extension modules work. These restrictions are typically a sideeffect of limitations of the *Python distribution* being used/targeted. These restrictions are documented in the sections below.

#### musl libc Linux Distributions Only Support Built-in Extension Modules

The Python distributions built against musl libc (build target \*-linux-musl) only support *built-in* extension modules.

This is because must libc binaries are statically linked and statically linked Linux binaries are incapable of calling dlopen() to load a shared library.

This means Python binaries built in this configuration cannot load *standalone* Python extension modules existing as separate files (.so files typically). This means PyOxidizer cannot consume Python wheels or other Python resource sources containing pre-built Python extension modules.

In order for PyOxidizer to support a Python extension module built for musl libc, it must compile that extension module from source and link the resulting object files / static library directly into the built binary and expose that extension module as a *built-in*. This is done using *Building with a Custom Distutils*.

#### Windows Static Distributions Only Support Built-in Extension Modules

The Windows standalone\_static distribution flavor only supports *built-in* extension modules and doesn't support loading shared library extension modules.

See the above section for implications on this.

The situation of having to rebuild Python extension modules on Windows is often more complicated than on Linux because oftentimes building extension modules on Windows isn't as trivial as on Linux. This is because many Windows environments don't have the correct version of Visual Studio or various library dependencies. If you want a turnkey experience for Windows packaging, it is recommended to use the standalone\_dynamic distribution flavor.

#### Loading Extension Modules from in-memory Location

When you attempt to add a *PythonExtensionModule* Starlark instance to the in-memory *resource location*, the request may or may not work depending on the state of the extension module and support from the Python distribution.

The in-memory resource location is interpreted by PyOxidizer as *load this extension from memory, without having a standalone file.* PyOxidizer will try its hardest to satisfy this request.

If the object files / static library of an extension module are known to PyOxidizer, these will be statically linked into the built binary and the extension module will be exposed as a *built-in* extension module.

If only a shared library is available for the extension module, PyOxidizer only supports loading shared libraries from memory on Windows standalone\_dynamic distributions: in all other platforms the request to load a shared library extension module is rejected.

Some extensions and shared libraries are known to not work when loaded from memory using the custom shared library loader used by PyOxidizer. For this reason, *allow\_in\_memory\_shared\_library\_loading* exists to control this behavior.

**Important:** Because the in-memory location for extension modules can be brittle, it is recommended to set a resources policy or add\_location\_fallback to allow extension modules to exist as standalone files. This will provide maximum compatibility with built Python extension modules and will reduce the complexity of packaging 3rd party extension modules.

#### 5.7.3 Extension Module Library Dependencies

PyOxidizer doesn't currently support resolving additional library dependencies from discovered extension modules outside of the Python distribution. For example, if your extension module foo.so has a run-time dependency on bar.so, PyOxidizer doesn't yet detect this and doesn't realize that bar.so needs to be handled.

This means that if you add a *PythonExtensionModule* Starlark type and this extension module depends on an additional library, PyOxidizer will likely not realize this and fail to distribute that additional library dependency with your application.

If your Python extensions depend on additional libraries, you may need to manually add these files to your installation via custom Starlark code.

Note that if your shared library exists as a file in Python package (a directory with <u>\_\_init\_\_</u>.py somewhere in the hierarchy), PyOxidizer's resource scanning may detect the shared library as a *PythonPackageResource* and package this resource. However, the packaged resource won't be flagged as a shared library. This means that the run-time importer won't identify the shared library dependency and won't take steps to ensure it is available/loaded before the extension is loaded. This means that the shared library loading needs to be handled by the operating system's default rules. And this means that the shared library file must exist on the filesystem, next to a file-based extension module.

### 5.7.4 Building with a Custom Distutils

If PyOxidizer is not able to reuse an existing shared library extension module or the build configuration is forcing an extension to be built as a *built-in*, PyOxidizer attempts to compile the extension module from source so that it can be statically linked as a *built-in*.

The way PyOxidizer achieves this is a bit crude, but often effective.

When PyOxidizer invokes pip or setup.py to build a package, it installs a modified version of distutils into the invoked Python's sys.path. This modified distutils changes the behavior of some key build steps (notably

how C extensions are compiled) such that the build emits artifacts that PyOxidizer can statically link into a custom binary.

For example, on Linux, PyOxidizer copies the intermediate object files produced by the build and links them into the binary containing the generated libpython. PyOxidizer completely ignores the shared library that is or would typically be produced.

If setup.py scripts are following the traditional pattern of using distutils.core.Extension to define extension modules, things tend to *just work* (assuming extension modules are supported by PyOxidizer for the target platform). However, if setup.py scripts are doing their own monkeypatching of distutils, rely on custom build steps or types to compile extension modules, or invoke separate Python processes to interact with distutils, things may break.

The easiest way to avoid the pitfalls of a custom distutils build is to not attempt to produce a statically linked binary: use a standalone\_dynamic distribution flavor that supports loading extension modules from files.

Until PyOxidizer supports telling it additional object files or static libraries to link into a binary, there's no easy workaround aside from giving up on a statically linked binary. Better support will hopefully be present in future versions of PyOxidizer.

# 5.8 Trimming Unused Resources

By default, packaging rules are very aggressive about pulling in resources such as Python modules. For example, the entire Python standard library is embedded into the binary by default. These extra resources take up space and can make your binary significantly larger than it could be.

It is often desirable to *prune* your application of unused resources. For example, you may wish to only include Python modules that your application uses. This is possible with PyOxidizer.

Essentially, all strategies for managing the set of packaged resources boil down to crafting config file logic that chooses which resources are packaged.

But maintaining explicit lists of resources can be tedious. PyOxidizer offers a more automated approach to solving this problem.

The *PythonInterpreterConfig* type defines a write\_modules\_directory\_env setting, which when enabled will instruct the embedded Python interpreter to write the list of all loaded modules into a randomly named file in the directory identified by the environment variable defined by this setting. For example, if you set write\_modules\_directory\_env="PYOXIDIZER\_MODULES\_DIR" and then run your binary with PYOXIDIZER\_MODULES\_DIR=~/tmp/dump-modules, each invocation will write a ~/tmp/ dump-modules/modules-\* file containing the list of Python modules loaded by the Python interpreter.

One can therefore use write\_modules\_directory\_env to produce files that can be referenced in a different build *target* to filter resources through a set of *only include* names.

TODO this functionality was temporarily dropped as part of the Starlark port.

# 5.9 Performance of Built Binaries

Binaries built with PyOxidizer tend to run faster than those executing via a normal python interpreter. There are a few reasons for this.

### 5.9.1 Resources Data Compiled Into Binary

Traditionally, when Python needs to import a module, it traverses the entries on sys.path and queries the filesystem to see whether a .pyc file, .py file, etc are available until it finds a suitable file to provide the Python module data. If you trace the system calls of a Python process (e.g. strace -f python3 ...), you will see tons of lstat(), open(), and read() calls performing filesystem I/O.

While filesystems cache the data behind these I/O calls, every time Python looks up data in a file the process needs to context switch into the kernel and then pass data back to Python. Repeated thousands of times - or even millions of times across hundreds or thousands of process invocations - the few microseconds of overhead plus the I/O overhead for a cache miss can add up to significant overhead!

When binaries are built with PyOxidizer, all available Python resources are discovered at build time. An index of these resources along with the raw resource data is packed - often into the executable itself - and made available to PyOxidizer's *custom importer*. When PyOxidizer services an import statement, looking up a module is effectively looking up a key in a dictionary: there is no explicit filesystem I/O to discover the location of a resource.

PyOxidizer's packed resources data supports storing raw resource data inline or as a reference via a filesystem path.

If inline storage is used, resources are effectively loaded from memory, often using 0-copy. There is no explicit filesystem I/O. The only filesystem I/O that can occur is indirect, as the operating system pages a memory page on first access. But this all happens in the kernel memory subsystem and is typically faster than going through a functionally equivalent system call to access the filesystem.

If filesystem paths are stored, the only filesystem I/O we require is to open() the file and read() its file descriptor: all filesystem I/O to locate the backing file is skipped, along with the overhead of any Python code performing this discovery.

We can attempt to isolate the effect of in-memory module imports by running a Python script that attempts to import the entirety of the Python standard library. This test is a bit contrived. But it is effective at demonstrating the performance difference.

Using a stock python3.7 executable and 2 PyOxidizer executables - one configured to load the standard library from the filesystem using Python's default importer and another from memory:

```
$ hyperfine -m 50 -- '/usr/local/bin/python3.7 -S import_stdlib.py' import-stdlib-
→filesystem import-stdlib-memory
Benchmark #1: /usr/local/bin/python3.7 -S import_stdlib.py
 Time (mean \pm \sigma): 258.8 ms \pm 8.9 ms [User: 220.2 ms, System: 34.4 ms]
                        247.7 ms ... 310.5 ms
 Range (min ... max):
                                                 50 runs
Benchmark #2: import-stdlib-filesystem
 Time (mean \pm \sigma): 249.4 ms \pm 3.7 ms
                                              [User: 216.3 ms, System: 29.8 ms]
 Range (min ... max): 243.5 ms ... 258.5 ms
                                                 50 runs
Benchmark #3: import-stdlib-memory
 Time (mean \pm \sigma): 217.6 ms \pm
                                    6.4 ms [User: 200.4 ms, System: 13.7 ms]
 Range (min ... max): 207.9 ms ... 243.1 ms
                                                  50 runs
Summary
  'import-stdlib-memory' ran
    1.15 \pm 0.04 times faster than 'import-stdlib-filesystem'
    1.19 \pm 0.05 times faster than '/usr/local/bin/python3.7 -S import_stdlib.py'
```

We see that the PyOxidizer executable using the standard Python importer has very similar performance to python3.7. But the PyOxidizer executable importing from memory is clearly faster. These measurements were obtained on macOS and the import\_stdlib.py script imports 506 modules.

A less contrived example is running the test harness for the Mercurial version control tool. Mercurial's test harness creates tens of thousands of new processes that start Python interpreters. So a few milliseconds of overhead starting

interpreters or loading modules can translate to several seconds.

We run the full Mercurial test harness on Linux on a Ryzen 3950X CPU using the following variants:

- hg script with a #!/path/to/python3.7 line (traditional)
- hg PyOxidizer executable using Python's standard filesystem import (oxidized)
- hg PyOxidizer executable using filesystem-relative resource loading (filesystem)
- hg PyOxidizer executable using in-memory resource loading (in-memory)

The results are quite clear:

Variant	CPU Time (s)	Delta (s)	% Orig
traditional	11,287	0	100
oxidized	10,735	-552	95.1
filesystem	10,186	-1,101	90.2
in-memory	9,883	-1,404	87.6

These results help us isolate specific areas of speedups:

- *oxidized* over *traditional* is a rough proxy for the benefits of python -S over python. Although there are other factors at play that may be influencing the numbers.
- *filesystem* over *oxidized* isolates the benefits of using PyOxidizer's importer instead of Python's default importer. The performance wins here are due to a) avoiding excessive I/O system calls to locate the paths to resources and b) functionality being implemented in Rust instead of Python.
- *in-memory* over *filesystem* isolates the benefits of avoiding explicit filesystem I/O to load Python resources. The Rust code backing these 2 variants is very similar. The only meaningful difference is that *in-memory* constructs a Python object from a memory address and *filesystem* must open and read a file using standard OS mechanisms before doing so.

From this data, one could draw a few conclusions:

- Processing of the site module during Python interpreter initialization can add substantial overhead.
- Maintaining an index of Python resources such that you can avoid discovery via filesystem I/O provides a meaningful speedup.
- Loading Python resources from an in-memory data structure is faster than incurring explicit filesystem I/O to do so.

#### 5.9.2 Ignoring site

In its default configuration, binaries produced with PyOxidizer configure the embedded Python interpreter differently from how a python is typically configured.

Notably, PyOxidizer disables the importing of the site module by default (making it roughly equivalent to python -S). The site module does a number of things, such as look for .pth files, looks for site-packages directories, etc. These activities can contribute substantial overhead, as measured through a normal python3.7 executable on macOS:

```
$ hyperfine -m 500 -- '/usr/local/bin/python3.7 -c 1' '/usr/local/bin/python3.7 -S -c_

\rightarrow1'
Benchmark #1: /usr/local/bin/python3.7 -c 1

Time (mean ± \sigma): 22.7 ms ± 2.0 ms [User: 16.7 ms, System: 4.2 ms]

Range (min ... max): 18.4 ms ... 32.7 ms 500 runs
```

(continues on next page)

(continued from previous page)

```
Benchmark #2: /usr/local/bin/python3.7 -S -c 1

Time (mean \pm \sigma): 12.7 ms \pm 1.1 ms [User: 8.2 ms, System: 2.9 ms]

Range (min ... max): 9.8 ms ... 16.9 ms 500 runs

Summary

'/usr/local/bin/python3.7 -S -c 1' ran

1.78 \pm 0.22 times faster than '/usr/local/bin/python3.7 -c 1'
```

Shaving ~10ms off of startup overhead is not trivial!

# 5.10 Packaging Pitfalls

While PyOxidizer is capable of building fully self-contained binaries containing a Python application, many Python packages and applications make assumptions that don't hold inside PyOxidizer. This section talks about all the things that can go wrong when attempting to package a Python application.

### 5.10.1 C and Other Native Extension Modules

Many Python packages compile *extension modules* to native code. (Typically C is used to implement extension modules.)

PyOxidizer has varying levels of support for Python extension modules. In many cases, everything *just works*. But there are known incompatibilities and corner cases. See *Working with Python Extension Modules* for details.

### 5.10.2 Identifying PyOxidizer

Python code may want to know whether it is running in the context of PyOxidizer.

At packaging time, pip and setup.py invocations made by PyOxidizer should set a PYOXIDIZER=1 environment variable. setup.py scripts, etc can look for this environment variable to determine if they are being packaged by PyOxidizer.

At run-time, PyOxidizer will always set a sys.oxidized attribute with value True. So, Python code can test whether it is running in PyOxidizer like so:

```
import sys
if getattr(sys, 'oxidized', False):
    print('running in PyOxidizer!')
```

#### 5.10.3 Incorrect Resource Identification

PyOxidizer has custom code for scanning for and indexing files as specific Python resource types. This code is somewhat complex and nuanced and there are known bugs that will cause PyOxidizer to fail to identify or classify a file appropriately.

To help debug problems with this code, the pyoxidizer find-resources command can be employed. See *Debugging Resource Scanning and Identification with find-resources* for more.

**Important:** Please file a bug to report problems!

See Classified Resources Versus Files for more on this topic.

# 5.11 Masquerading As Other Packaging Tools

Tools to package and distribute Python applications existed several years before PyOxidizer. Many Python packages have learned to perform special behavior when the \_fingerprint\* of these tools is detected at run-time.

First, PyOxidizer has its own fingerprint: sys.oxidized = True. The presence of this attribute can indicate an application running with PyOxidizer. Other applications are discouraged from defining this attribute.

Since PyOxidizer's run-time behavior is similar to other packaging tools, PyOxidizer supports falsely identifying itself as these other tools by emulating their fingerprints.

The EmbbedPythonConfig configuration section defines the boolean flag sys\_frozen to control whether sys. frozen = True is set. This can allow PyOxidizer to advertise itself as a *frozen* application.

In addition, the sys\_meipass boolean flag controls whether a sys.\_MEIPASS = <exe directory> attribute is set. This allows PyOxidizer to masquerade as having been built with PyInstaller.

**Warning:** Masquerading as other packaging tools is effectively lying and can be dangerous, as code relying on these attributes won't know if it is interacting with PyOxidizer or some other tool. It is recommended to only set these attributes to unblock enabling packages to work with PyOxidizer until other packages learn to check for sys.oxidized = True. Setting sys.\_MEIPASS is definitely the more risky option, as a case can be made that PyOxidizer should set sys.frozen = True by default.

# 5.12 Portability of Binaries Built with PyOxidizer

Binary portability refers to the property that a binary built in machine/environment X is able to run on machine/environment Y. In other words, you've achieved binary portability if you are able to copy a binary to another machine and run it without modifications.

It is exceptionally difficult to achieve high levels of binary portability for various reasons.

PyOxidizer is capable of building binaries that are highly *portable*. However, the steps for doing so can be nuanced and vary substantially by operating system and target platform. This document attempts to capture the various steps and caveats involved.

**Important:** Please create issues at https://github.com/indygreg/PyOxidizer/issues when documentation on this page is inaccurate or lacks critical details.

#### 5.12.1 Using pyoxidizer analyze For Assessing Binary Portability

The pyoxidizer analyze command can be used to analyze the contents of executables and libraries. It can be used as a PyOxidizer-specific tool for assessing the portability of built binaries.

For example, for ELF binaries (the binary format used on Linux), this command will list all shared library dependencies and analyze glibc symbol versions and print out which Linux distribution versions it thinks the binary is compatible with.

Note: pyoxidizer analyze is not yet feature complete on all platforms.

### 5.12.2 Python Distribution Versus Built Application Portability

PyOxidizer ships with specially built Python distributions that are highly portable. See *Available Python Distributions* for the full list of these distributions and *Binary Portability of Distributions* for details on the portability of these Python distributions.

Generally speaking, you don't have to worry about the portability of the Python distributions because the distributions tend to *just work*.

**Important:** The machine and environment you use to run pyoxidizer has critical implications for the portability of built binaries.

When you use PyOxidizer to produce a new binary (an executable or library), you are compiling *new* code and linking it in an environment that is different from the specialized environment used to build the built-in Python distributions. This means that the binary portability of your built binary is effectively defined by the environment pyoxidizer was run from.

#### 5.12.3 Windows

The built-in Python distributions have a run-time dependency on various DLLs. All 3rd party DLLs (OpenSSL, SQLite3, etc) required by Python extensions are provided by the built-in distributions.

Many DLL dependencies should be present in any Windows installation.

The Python distributions also have a dependency on the Visual Studio C++ Runtime. You will need to distribute a copy of vcruntimeXXX.dll alongside your binary or trigger the install of the Visual Stdio C++ Redistributable in your application installer so the dependency is managed at the system level. (Installing the redistributable via an installer is preferred.)

There is also currently a dependency on the Universal C Runtime (UCRT).

PyOxidizer will eventually make producing Windows installers from packaged applications turnkey (#279). Until that time arrives, see the Microsoft documentation on deployment considerations for Windows binaries. The Dependency Walker tool is also useful for analyzing DLL dependencies.

Windows binaries tend to be highly portable by default. If you follow Microsoft's guidelines and install all required DLLs, you should be set.

#### 5.12.4 macOS

The built-in Python distributions are built with MACOSX\_DEPLOYMENT\_TARGET=10.9, so they should be compatible with macOS versions 10.9 and newer.

The Python distribution has dependencies against a handful of system libraries and frameworks. These frameworks should be present on all macOS installations.

From your build environment, you may want to also ensure MACOSX\_DEPLOYMENT\_TARGET is set to ensure references to newer macOS SDK features aren't present.

Apple's Xcode documentation has various guides useful for further consideration.

### 5.12.5 Linux

Linux is the most difficult platform to tackle for binary portability. There's a strongly held attitude that binaries should be managed as packages by the operating system and these packages are built in such a way that the package manager handles all the details for you. If you stray from the *paved road* and choose not to use the package manager provided by your operating system with the package sources configured by default, things get very challenging very quickly.

The best way to produce a portable Linux binary is to produce a fully statically-linked binary. There are no shared libraries to worry about and generally speaking these binaries *just work*. See *Building Fully Statically Linked Binaries on Linux* for more.

If you produce a dynamic binary with library dependencies, things are complicated.

Nearly every binary built on Linux will require linking against libc and will require a symbol provided by glibc. glibc versions it symbols. And when the linker resolves those symbols at link time, it usually uses the version of glibc being linked against. For example, if you link on a machine with glibc 2.19, the symbol versions in the produced binary will be against version 2.19 and the binary will load against glibc versions >=2.19. But if you link on a machine with glibc 2.29, symbol versions are against version 2.29 and you can only load against versions >= 2.29.

This means that to ensure maximum portability, you want to link against old glibc symbol versions. While it is possible to use old symbol versions when a more modern glibc is present, the path of least resistance is to build in an environment that has an older glibc.

The built-in Linux distributions use Debian 8 (Jessie) as their build environment. So a Debian 8 build environment is a good candidate to build on. Ubuntu 14.04, OpenSUSE 13.2, OpenSUSE 42.1, RHEL/CentOS 7, and Fedora 21 (glibc 2.20) are also good candidates for build environments.

Of course, if you are producing distribution-specific binaries and/or control installation (so e.g. dependencies are installed automatically), this matters less to you.

Again, the pyoxidizer analyze command can be very useful for inspecting binaries for portability and alerting you to any potential issues.

# 5.13 Static Linking

This document describes how to statically link binaries embedding Python.

See also *Working with Python Extension Modules* for extensive documentation about extension modules, which are often a pain point when it comes to static linking.

### 5.13.1 Building Fully Statically Linked Binaries on Linux

It is possible to produce a fully statically linked executable embedding Python on Linux. The produced binary will have no external library dependencies nor will it even support loading dynamic libraries. In theory, the executable can be copied between Linux machines and it will *just work*.

Building such binaries requires using the x86\_64-unknown-linux-musl Rust toolchain target. Using pyoxidizer:

\$ pyoxidizer build --target x86\_64-unknown-linux-musl

Specifying --target x86\_64-unknown-linux-musl will cause PyOxidizer to use a Python distribution built against musl libc as well as tell Rust to target *musl on Linux*.

Targeting musl requires that Rust have the musl target installed. Standard Rust on Linux installs typically do not have this installed! To install it:

```
$ rustup target add x86_64-unknown-linux-musl
info: downloading component 'rust-std' for 'x86_64-unknown-linux-musl'
info: installing component 'rust-std' for 'x86_64-unknown-linux-musl'
```

If you don't have the musl target installed, you get a build time error similar to the following:

```
error[E0463]: can't find crate for `std`
    |
    = note: the `x86_64-unknown-linux-musl` target may not be installed
```

But even installing the target may not be sufficient! The standalone Python builds are using a modern version of musl and the Rust musl target must also be using this newer version or else you will see linking errors due to missing symbols. For example:

```
/build/Python-3.7.3/Python/bootstrap_hash.c:132: undefined reference to `getrandom'
/usr/bin/ld: /build/Python-3.7.3/Python/bootstrap_hash.c:132: undefined reference to_
    `getrandom'
/usr/bin/ld: /build/Python-3.7.3/Python/bootstrap_hash.c:136: undefined reference to_
    `getrandom'
/usr/bin/ld: /build/Python-3.7.3/Python/bootstrap_hash.c:136: undefined reference to_
    `getrandom'
```

Rust 1.37 or newer is required for the modern musl version compatibility. Rust 1.37 is Rust Nightly until July 4, 2019, at which point it becomes Rust Beta. It then becomes Rust Stable on August 15, 2019. You may need to override the Rust toolchain used to build your project so Rust 1.37+ is used. For example:

```
$ rustup override set nightly
$ rustup target add --toolchain nightly x86_64-unknown-linux-musl
```

This will tell Rust that the nightly toolchain should be used for the current directory and to install musl support for the nightly toolchain.

Then you can build away:

Congratulations, you've produced a fully statically linked executable containing a Python application!

**Important:** There are reported performance problems with Python linked against musl libc. Application maintainers are therefore highly encouraged to evaluate potential performance issues before distributing binaries linked against musl libc.

It's worth noting that in the default configuration PyOxidizer binaries will use jemalloc for memory allocations, bypassing musl's apparently slower memory allocator implementation. This *may* help mitigate reported performance issues.

# 5.13.2 Implications of Static Linking

Most Python distributions rely heavily on dynamic linking. In addition to python frequently loading a dynamic libpython, many C extensions are compiled as standalone shared libraries. This includes the modules \_ctypes, \_json, \_sqlite3, \_ssl, and \_uuid, which provide the native code interfaces for the respective non-\_ prefixed modules which you may be familiar with.

These C extensions frequently link to other libraries, such as libffi, libsqlite3, libssl, and libcrypto. And more often than not, that linking is dynamic. And the libraries being linked to are provided by the system/environment Python runs in. As a concrete example, on Linux, the \_ssl module can be provided by \_ssl. cpython-37m-x86\_64-linux-gnu.so, which can have a shared library dependency against libssl.so. 1.1 and libcrypto.so.1.1, which can be located in /usr/lib/x86\_64-linux-gnu or a similar location under /usr.

When Python extensions are statically linked into a binary, the Python extension code is part of the binary instead of in a standalone file.

If the extension code is linked against a static library, then the code for that dependency library is part of the extension/binary instead of dynamically loaded from a standalone file.

When PyOxidizer produces a fully statically linked binary, the code for these 3rd party libraries is part of the produced binary and not loaded from external files at load/import time.

There are a few important implications to this.

One is related to security and bug fixes. When 3rd party libraries are provided by an external source (typically the operating system) and are dynamically loaded, once the external library is updated, your binary can use the latest version of the code. When that external library is statically linked, you need to rebuild your binary to pick up the latest version of that 3rd party library. So if e.g. there is an important security update to OpenSSL, you would need to ship a new version of your application with the new OpenSSL in order for users of your application to be secure. This shifts the security onus from e.g. your operating system vendor to you. This is less than ideal because security updates are one of those problems that tend to benefit from greater centralization, not less.

It's worth noting that PyOxidizer's library security story is very similar to that of containers (e.g. Docker images). If you are OK distributing and running Docker images, you should be OK with distributing executables built with PyOxidizer.

Another implication of static linking is licensing considerations. Static linking can trigger stronger licensing protections and requirements. Read more at *Licensing Considerations*.

# 5.14 Licensing Considerations

Any time you link libraries together or distribute software, you need to be concerned with the licenses of the underlying code. Some software licenses - like the GPL - can require that any code linked with them be subject to the license and therefore be made open source. In addition, many licenses require a license and/or copyright notice be attached to works that use or are derived from the project using that license. So when building or distributing **any** software, you need to be cognizant about all the software going into the final work and any licensing terms that apply. Binaries produced with PyOxidizer are no different!

PyOxidizer and the code it uses in produced binaries is licensed under the Mozilla Public License version 2.0. The licensing terms are generally pretty favorable. (If the requirements are too strong, the code that ships with binaries could potentially use a *weaker* license. Get in touch with the project author.)

The Rust code PyOxidizer produces relies on a handful of 3rd party Rust crates. These crates have various licenses. We recommend using the cargo-license, cargo-tree, and cargo-lichking tools to examine the Rust crate dependency tree and their respective licenses. The cargo-lichking tool can even assemble licenses of Rust dependencies automatically so you can more easily distribute those texts with your application!

As cool as these Rust tools are, they don't include licenses for the Python distribution, the libraries its extensions link against, nor any 3rd party Python packages you may have packaged.

Python and its various dependencies are governed by a handful of licenses. These licenses have various requirements and restrictions.

At the very minimum, the binary produced with PyOxidizer will have a Python distribution which is governed by a license. You will almost certainly need to distribute a copy of this license with your application.

Various C-based extension modules part of Python's standard library link against other C libraries. For self-contained Python binaries, these libraries will be statically linked if they are present. That can trigger *stronger* license protections. For example, if all extension modules are present, the produced binary may contain a copy of the GPL 3.0 licensed readline and gdbm libraries, thus triggering strong copyleft protections in the GPL license.

**Important:** It is critical to audit which Python extensions and packages are being packaged because of licensing requirements of various extensions.

Consider using a package such as pip-licenses to generate a license report for your Python packages.

### 5.14.1 Showing Python Distribution Licenses

The special Python distributions that PyOxidizer consumes can annotate licenses of software within.

The pyoxidizer python-distribution-licenses command can display the licenses for the Python distribution and libraries it may link against. This command can be used to evaluate which extensions meet licensing requirements and what licensing requirements apply if a given extension or library is used.

# 5.15 Terminfo Database

Note: This content is not relevant to Windows.

If your application interacts with terminals (e.g. command line tools), your application may require the availability of a terminfo database so your application can properly interact with the terminal. The absence of a terminal database can result in the inability to properly colorize text, the backspace and arrow keys not working as expected, weird behavior on window resizing, etc. A terminfo database is also required to use curses or readline module functionality without issue.

UNIX like systems almost always provide a terminfo database which says which features and properties various terminals have. Essentially, the TERM environment variable defines the current terminal [emulator] in use and the terminfo database converts that value to various settings.

From Python, the neurses library is responsible for consulting the terminfo database and determining how to interact with the terminal. This interaction with the neurses library is typically performed from the \_eurses, \_eurses\_panel, and \_readline C extensions. These C extensions are wrapped by the user-facing curses and readline Python modules. And these Python modules can be used from various functionality in the Python standard library. For example, the readline module is used to power pdb.

**PyOxidizer applications do not ship a terminfo database.** Instead, applications rely on the terminfo database on the executing machine. (Of course, individual applications could ship a terminfo database if they want: the functionality just isn't included in PyOxidizer by default.) The reason PyOxidizer doesn't ship a terminfo database is that terminal configurations are very system and user specific: PyOxidizer wants to respect the configuration of the environment in which applications run. The best way to do this is to use the terminfo database on the executing machine instead of providing a static database that may not be properly configured for the run-time environment.

PyOxidizer applications have the choice of various modes for resolving the terminfo database location. This is facilitated mainly via the *terminfo\_resolution* PythonInterpreterConfig.terminfo\_resolution config setting.

By default, when Python is initialized PyOxidizer will try to identify the current operating system and choose an appropriate set of well-known paths for that operating system. If the operating system is well-known (such as a Debian-based Linux distribution), this set of paths is fixed. If the operating system is not well-known, PyOxidizer will look for terminfo databases at common paths and use whatever paths are present.

If all goes according to plan, the default behavior *just works*. On common operating systems, the cost to the default behavior is reading a single file from the filesystem (in order to resolve the operating system). The overhead should be negligible. For unknown operating systems, PyOxidizer may need to stat() ~10 paths looking for the terminfo database. This should also complete fairly quickly. If the overhead is a concern for you, it is recommended to build applications with a fixed path to the terminfo database.

Under the hood, when PyOxidizer resolves the terminfo database location, it communicates these paths to neurses by setting the TERMINFO\_DIRS environment variable. If the TERMINFO\_DIRS environment variable is already set at application run-time, PyOxidizer will **never** overwrite it.

The neurses library that PyOxidizer applications ship with is also configured to look for a terminfo database in the current user's home directory (HOME environment variable) by default, specifically \$HOME/.terminfo). Support for termcap databases is not enabled.

**Note:** terminfo database behavior is intrinsically complicated because various operating systems do things differently. If you notice oddities in the interaction of PyOxidizer applications with terminals, there's a good chance you found a deficiency in PyOxidizer's terminal detection logic (which is located in the pyembed::osutils Rust module).

Please report terminal interaction issues at https://github.com/indygreg/PyOxidizer/issues.

# 5.16 Building an Executable that Behaves Like python

It is possible to use PyOxidizer to build an executable that would behave like a typical python executable would.

To start, initialize a new config file:

\$ pyoxidizer init-config-file python

Then, we'll want to modify the pyoxidizer.bzl configuration file to look something like the following:

```
def make_dist():
    return default_python_distribution()

def make_exe(dist):
    policy = dist.make_python_packaging_policy()
    policy.extension_module_filter = "all"
    policy.include_distribution_resources = True

    # Add resources to the filesytem, next to the built executable.
    # You can add resources to memory too. But this makes the install
    # layout somewhat consistent with what Python expects.
    policy.resources_location = "filesystem-relative:lib"
    python_config = dist.make_python_interpreter_config()
```

(continues on next page)

(continued from previous page)

```
# This is the all-important line to make the embedded Python interpreter
    # behave like `python`.
    python_config.config_profile = "python"
    # Enable the stdlib path-based importer.
    python_config.filesystem_importer = True
    # You could also disable the Rust importer if you really want your
    # executable to behave like `python`.
    # python_config.oxidized_importer = False
    exe = dist.to_python_executable(
        name="python3",
        packaging_policy = policy,
        config = python_config,
    )
    return exe
def make_embedded_resources(exe):
    return exe.to_embedded_resources()
def make_install(exe):
    files = FileManifest()
    files.add_python_resource(".", exe)
    return files
register_target("dist", make_dist)
register_target("exe", make_exe, depends=["dist"])
register_target("resources", make_embedded_resources, depends=["exe"], default_build_
→script=True)
register_target ("install", make_install, depends=["exe"], default=True)
resolve_targets()
```

(The above code is dedicated to the public domain and can be used without attribution.)

From there, build/run from the config:

```
$ cd python
$ pyoxidizer build
...
$ pyoxidizer run
...
Python 3.8.6 (default, Oct 3 2020, 20:48:20)
[Clang 10.0.1 ] on linux
Type "help", "copyright", "credits" or "license" for more information.
>>>
```

#### 5.16.1 Resource Loading Caveats

PyOxidizer's configuration defaults are opinionated about how resources are loaded by default. In the default configuration, the Python distribution's resources are indexed and loaded via oxidized\_importer at run-time. This behavior is obviously different from what a standard python executable would do. If you want the built executable to behave like python would and use the standard library importers, you can disable oxidized\_importer by setting *oxidized\_importer* to False.

Another caveat is that indexed resources are always embedded in the built executable. This may bloat the size of the executable. This will eventually be addressed by *Standalone Resource Files*.

# 5.16.2 Binary Portability

A python-like executable built with PyOxidizer may not *just work* when copied to another machine. See *Portability of Binaries Built with PyOxidizer* to learn more about the portability of binaries built with PyOxidizer.

# CHAPTER 6

# oxidized\_importer Python Extension

oxidized\_importer is a Python extension module maintained as part of the PyOxidizer project that allows you to:

- Install a custom, high-performance module importer (OxidizedFinder) to service Python import statements and resource loading (potentially from memory).
- Scan the filesystem for Python resources (source modules, bytecode files, package resources, distribution metadata, etc) and turn them into Python objects.
- Serialize Python resource data into an efficient binary data structure for loading into an OxidizedFinder instance. This facilitates producing a standalone *resources blob* that can be distributed with a Python application which contains all the Python modules, bytecode, etc required to power that application.

oxidized\_importer is automatically compiled into applications built with PyOxidizer. It can also be built as a standalone extension module and used with regular Python installs.

# 6.1 Getting Started

#### 6.1.1 Requirements

oxidized\_importer requires CPython 3.8 or newer. This is because it relies on modern C and Python standard library APIs only available in that version.

Building oxidized\_importer from source requires a working Rust toolchain for the target platform.

#### 6.1.2 Installing from PyPI

oxidized\_importer is available on PyPI. This means that installing is as simple as:

```
$ pip3 install oxidized_importer
```

### 6.1.3 Compiling from Source

To build from source, obtain a clone of PyOxidizer's Git repository and run the setup.py script or use pip to build the Python project in the root of the repository. e.g.:

```
$ python3.8 setup.py build_ext -i
$ python3.8 setup.py install
$ pip3.8 install .
$ pip3.8 wheel .
```

The setup.py is pretty minimal and is a thin wrapper around cargo build for the underlying Rust project. If you want to build using Rust's standard toolchain, do something like the following:

```
$ cd oxidized-importer
$ cargo build --release
```

If you don't have a Python 3.8 python3 executable in your PATH, you will need to tell the Rust build system which python3 executable to use to help derive the build configuration for the Python extension:

\$ PYTHON\_SYS\_EXECUTABLE=/path/to/python3.8 cargo build

#### 6.1.4 Using

To use oxidized\_importer, simply import the module:

```
import oxidized_importer
```

To register a custom importer with Python, do something like the following:

```
import sys
import oxidized_importer
finder = oxidized_importer.OxidizedFinder()
# You want to register the finder first so it has the highest priority.
sys.meta_path.insert(0, finder)
```

To get performance benefits of loading modules and resources from memory, you'll need to index resources with the OxidizedFinder, serialize that data out, then load that data into a new OxidizedFinder instance. See *Freezing Applications with oxidized\_importer* for more detailed examples.

# 6.2 Python Meta Path Finders

Python allows providing custom Python types to handle the low-level machinery behind the import statement. The way this works is a *meta path finder* instance (as defined by the importlib.abc.MetaPathFinder interface) is registered on sys.meta\_path. When an import is serviced, Python effectively iterates the objects on sys.meta\_path and asks each one *can you service this request* until one does.

These *meta path finder* not only service basic Python module loading, but they can also facilitate loading resource files and package metadata. There are a handful of optional methods available on implementations.

This documentation will often refer to a *meta path finder* as an *importer*, because it is primarily used for *importing* Python modules.

Normally when you start a Python process, the Python interpreter itself will install 3 *meta path finders* on sys. meta\_path before your code even has a chance of running:

- **BuiltinImporter** Handles importing of *built-in* extension modules, which are compiled into the Python interpreter. These include modules like sys.
- **FrozenImporter** Handles importing of *frozen* bytecode modules, which are compiled into the Python interpreter. This *finder* is typically only used to initialize Python's importing mechanism.
- **PathFinder** Handles filesystem-based loading of resources. This is what is used to import .py and .pyc files. It also handles .zip files. This is the *meta path finder* that most imports are traditionally serviced by. It queries the filesystem at import time to find and load resources.

# 6.3 OxidizedFinder Python Type

oxidized\_importer.OxidizedFinder is a Python type that implements a custom *meta path finder*. Oxidized is in its name because it is implemented in Rust.

Unlike traditional *meta path finders* which have to dynamically discover resources (often by scanning the filesystem), OxidizedFinder instances maintain an *index* of known resources. When a resource is requested, OxidizedFinder can retrieve that resource by effectively performing 1 or 2 lookups in a Rust HashMap. This makes resource resolution extremely efficient.

Instances of OxidizedFinder are optionally bound to a binary blob holding *packed resources data*. This is a custom serialization format for expressing Python modules (source and bytecode), Python extension modules, resource files, shared libraries, etc. This data format along with a Rust library for interacting with it are defined by the python-packed-resources crate.

When an OxidizedFinder instance is created, the *packed resources data* is parsed into a Rust data structure. On a modern machine, parsing this resources data for the entirety of the Python standard library takes ~1 ms.

OxidizedFinder instances can index *built-in* extension modules and *frozen* modules, which are compiled into the Python interpreter. This allows OxidizedFinder to subsume functionality normally provided by the BuiltinImporter and FrozenImporter *meta path finders*, allowing you to potentially replace sys. meta\_path with a single instance of OxidizedFinder.

#### 6.3.1 OxidizedFinder in PyOxidizer Applications

When running from an application built with PyOxidizer (or using the pyembed crate directly), an OxidizedFinder instance will (likely) be automatically registered as the first element in sys.meta\_path when starting a Python interpreter.

You can verify this inside a binary built with PyOxidizer:

```
>>> import sys
>>> sys.meta_path
[<OxidizedFinder object at 0x7f16bb6f93d0>]
```

Contrast with a typical Python environment:

(continues on next page)

(continued from previous page)

```
<class '_frozen_importlib_external.PathFinder'>
```

The OxidizedFinder instance will (likely) be associated with resources data embedded in the binary.

This OxidizedFinder instance is constructed very early during Python interpreter initialization. It is registered on sys.meta\_path before the first import requesting a .py/.pyc is performed, allowing it to service every import except those from the very few *built-in extension modules* that are compiled into the interpreter and loaded as part of Python initialization (e.g. the sys module).

### 6.3.2 Python API

1

OxidizedFinder instances implement the following interfaces:

- importlib.abc.MetaPathFinder
- importlib.abc.Loader
- importlib.abc.InspectLoader
- importlib.abc.ExecutionLoader

See the importlib.abc documentation for more on these interfaces.

In addition to the methods on the above interfaces, the following methods defined elsewhere in importlib are exposed:

- get\_resource\_reader(fullname: str) -> importlib.abc.ResourceReader
- find\_distributions(context: Optional[DistributionFinder.Context]) ->
   [Distribution]

ResourceReader is documented alongside other importlib.abc interfaces. find\_distribution() is documented in importlib.metadata.

### 6.3.3 Non-importlib API

OxidizedFinder instances have additional functionality beyond what is defined by importlib. This functionality allows you to construct, inspect, and manipulate instances.

```
__new__(cls, ...)
```

New instances of OxidizedFinder can be constructed like normal Python types:

finder = OxidizedFinder()

The constructor takes the following named arguments:

- **resources\_data** Bytes-like *packed resources data* to parse. A reference to the passed in value will be stored internally in the constructed instance, as the memory needs to live for the lifetime of the OxidizedFinder instance.
- **resources\_file** A path-like object defining the filesystem path to a file containing *packed resources data*. If provided, the file will be opened and memory mapped and resources data will be parsed from it.

relative\_path\_origin A path-like object denoting the filesystem path that should be used as the *origin* value for relative path resources. Filesystem-based resources are stored as a relative path to an *anchor* value. This is that *anchor* value. If not specified, the directory of the current executable will be used.

See the python\_packed\_resources Rust crate for the specification of the binary data blob defining *packed resources data*.

**Important:** The *packed resources data* format is still evolving. It is recommended to use the same version of the oxidized\_importer extension to produce and consume this data structure to ensure compatibility.

#### indexed\_resources(self) -> List[OxidizedResource]

This method returns a list of resources that are indexed by the OxidizedFinder instance. It allows Python code to inspect what the finder knows about.

See OxidizedResource for more on the returned type.

#### add\_resource(self, resource: OxidizedResource)

This method registers an OxidizedResource instance with the finder, enabling the finder to use it to service lookups.

When an OxidizedResource is registered, its data is copied into the finder instance. So changes to the original OxidizedResource are not reflected on the finder. (This is because OxidizedFinder maintains an index and it is important for the data behind that index to not change out from under it.)

Resources are stored in an invisible hash map where they are indexed by the name attribute. When a resource is added, any existing resource under the same name has its data replaced by the incoming OxidizedResource instance.

If you have source code and want to produce bytecode, you can do something like the following:

```
def register_module(finder, module_name, source):
    code = compile(source, module_name, "exec")
    bytecode = marshal.dumps(code)
    resource = OxidizedResource()
    resource.name = module_name
    resource.is_module = True
    resource.is_module = True
    resource.in_memory_bytecode = bytecode
    resource.in_memory_source = source
    finder.add_resource(resource)
```

#### add\_resources(self, resources: List[OxidizedResource])

This method is syntactic sugar for calling add\_resource() for every item in an iterable. It is exposed because function call overhead in Python can be non-trivial and it can be quicker to pass in an iterable of OxidizedResource than to call add\_resource() potentially hundreds of times.

#### serialize\_indexed\_resources(self, ...) -> bytes

This method serializes all resources currently indexed by the instance into an opaque bytes instance. The returned data can be fed into a separate OxidizedFinder instance by passing it to \_\_new\_\_(cls, ...).

Arguments:

ignore\_builtin (bool) Whether to ignore builtin extension modules from the serialized data.

Default is True

ignore\_frozen (bool) Whether to ignore frozen extension modules from the serialized data.

Default is True.

Entries for *built-in* and *frozen* modules are ignored by default because they aren't portable, as they are compiled into the interpreter and aren't guaranteed to work from one Python interpreter to another. The serialized format does support expressing them. Use at your own risk.

# 6.4 OxidizedFinder Behavior and Compliance

OxidizedFinder strives to be as compliant as possible with other *meta path importers*. So generally speaking, the behavior as described by the importlib documentation should be compatible. In other words, things should mostly *just work* and any deviance from the importlib documentation constitutes a bug worth reporting.

That being said, OxidizedFinder's approach to loading resources is drastically different from more traditional means, notably loading files from the filesystem. PyOxidizer breaks a lot of assumptions about how things have worked in Python and there is some behavior that may seem odd or in violation of documented behavior in Python.

The sections below attempt to call out known areas where OxidizedFinder deviates from typical behavior.

### 6.4.1 \_\_file\_\_ and \_\_cached\_\_ Module Attributes

Python modules typically have a \_\_\_\_\_\_\_\_ attribute holding a str defining the filesystem path the source module was imported from (usually a path to a .py file). There is also the similar - but lesser known - \_\_\_\_\_\_ cached\_\_\_ attribute holding the filesystem path of the bytecode module (usually the path to a .pyc file).

**Important:** OxidizedFinder will not set either attribute when importing modules from memory.

These attributes are not set because it isn't obvious what the values should be! Typically, \_\_file\_\_ is used by Python as an anchor point to derive the path to some other file. However, when loading modules from memory, the traditional filesystem hierarchy of Python modules does not exist. In the opinion of PyOxidizer's maintainer, exposing \_\_file\_\_ would be *lying* and this would cause more potential for harm than good.

While we may make it possible to define \_\_\_\_\_\_\_(and \_\_\_\_\_\_) on modules imported from memory someday, we do not yet support this.

OxidizedFinder does, however, set \_\_\_\_\_\_file\_\_\_ and \_\_\_\_\_cached\_\_\_ on modules imported from the filesystem. See *Resource Locations* for more on registering files for filesystem loading. So, a workaround to restore these missing attributes is to avoid in-memory loading.

# 6.4.2 \_\_path\_\_ Module Attribute

Python modules that are also packages must have a <u>\_\_path\_\_</u> attribute containing an iterable of str. The iterable can be empty.

If a module is imported from the filesystem, OxidizedFinder will set \_\_\_path\_\_\_ to the parent directory of the module's file, just like the standard filesystem importer would.

If a module is imported from memory, \_\_path\_\_ will be set to the path of the current executable joined with the package name. e.g. if the current executable is /usr/bin/myapp and the module/package name is foo.bar, \_\_path\_\_ will be ["/usr/bin/myapp/foo/bar"]. On Windows, paths might look like C:\dev\myapp. exe\foo\bar.

Python's zipimport importer uses the same approach for modules imported from zip files, so there is precedence for OxidizedFinder doing things this way.

#### 6.4.3 ResourceReader Compatibility

ResourceReader has known compatibility differences with Python's default filesystem-based importer. See *Support for ResourceReader* for details.

#### 6.4.4 ResourceLoader Compatibility

The ResourceLoader interface is implemented but behavior of get\_data(path) has some variance with Python's filesystem-based importer.

See Support for ResourceLoader for details.

**Note:** ResourceLoader is deprecated as of Python 3.7. Code should be ported to ResourceReader / importlib.resources if possible.

#### 6.4.5 importlib.metadata Compatibility

OxidizedFinder implements find\_distributions() and therefore provides the required hook for importlib.metadata to resolve Distribution instances. However, the returned objects do not implement the full Distribution interface.

Here are the known differences between OxidizedDistribution and importlib.metadata. Distribution instances:

- locate\_file() is not defined.
- @classmethod from\_name() is not defined.
- @classmethod discover() is not defined.
- @staticmethod at() is not defined.
- Oproperty files raises NotImplementedError.

There are additional \_ prefixed attributes of importlib.metadata.Distribution that are not implemented. But we do not consider these part of the public API and don't feel they are worth calling out.

In addition, OxidizedFinder.find\_distributions() ignores the path attribute of the passed Context instance. Only the name attribute is consulted. If name is None, all packages with registered distribution files will be returned. Otherwise the returned list contains at most 1 PyOxidizerDistribution corresponding to the requested package name.

# 6.4.6 pkgutil Compatibility

The pkgutil package in Python's standard library reacts to special functionality on MetaPathFinder instances.

pkgutil.iter\_modules() attempts to use an iter\_modules() method to obtain results.

OxidizedFinder implements iter\_modules(prefix="") and pkgutil.iter\_modules() should work. However, there are some differences in behavior:

- iter\_modules() is defined to be a generator but OxidizedFinder.iter\_modules() returns a list. list is iterable and this difference should hopefully be a harmless implementation detail.
- pkgutil.iter\_modules() inspects sys.path\_importer\_cache as part of evaluating its path argument. However, OxidizedFinder does not populate sys.path\_importer\_cache, so path-based filtering via pkgutil.iter\_modules(path=...) will not work like it does with the standard library's importer.

# 6.5 oxidized\_importer Python Resource Types

The oxidized\_importer module defines Python types beyond OxidizedFinder. This page documents those types and their APIs.

**Important:** All types are backed by Rust structs and all properties return copies of the data. This means that if you mutate a Python variable that was obtained from an instance's property, that mutation won't be reflected in the backing Rust struct.

#### 6.5.1 OxidizedResource

The OxidizedResource Python type represents a resource that is indexed by a OxidizedFinder instance.

Each instance represents a named entity with associated metadata and data. e.g. an instance can represent a Python module with associated source and bytecode.

New instances can be constructed via OxidizedResource(). This will return an instance whose name = "" and all properties will be None or false.

#### **Properties**

The following properties/attributes exist on OxidizedResource instances:

- **is\_module** A bool indicating if this resource is a Python module. Python modules are backed by source or bytecode.
- **is\_builtin\_extension\_module** A bool indicating if this resource is a Python extension module built-in to the Python interpreter.
- **is\_frozen\_module** A bool indicating if this resource is a Python module whose bytecode is frozen into the Python interpreter.
- **is\_extension\_module** A bool indicating if this resource is a Python extension module.
- **is\_shared\_library** A bool indicating if this resource is a shared library.
- name The str name of the resource.
- **is\_package** A bool indicating if this resource is a Python package.

**is\_namespace\_package** A bool indicating if this resource is a Python namespace package.

in\_memory\_source bytes or None holding Python module source code that should be imported from memory.

in\_memory\_bytecode bytes or None holding Python module bytecode that should be imported from memory.

This is raw Python bytecode, as produced from the marshal module. .pyc files have a header before this data that will need to be stripped should you want to move data from a .pyc file into this field.

in\_memory\_bytecode\_opt1 bytes or None holding Python module bytecode at optimization level 1 that should be imported from memory.

This is raw Python bytecode, as produced from the marshal module. .pyc files have a header before this data that will need to be stripped should you want to move data from a .pyc file into this field.

in\_memory\_bytecode\_opt2 bytes or None holding Python module bytecode at optimization level 2 that should be imported from memory.

This is raw Python bytecode, as produced from the marshal module. .pyc files have a header before this data that will need to be stripped should you want to move data from a .pyc file into this field.

- **in\_memory\_extension\_module\_shared\_library** bytes or None holding native machine code defining a Python extension module shared library that should be imported from memory.
- in\_memory\_package\_resources dict[str, bytes] or None holding resource files to make available to the importlib.resources APIs via in-memory data access. The name of this object will be a Python package name. Keys in this dict are virtual filenames under that package. Values are raw file data.
- in\_memory\_distribution\_resources dict[str, bytes] or None holding resource files to make available to the importlib.metadata API via in-memory data access. The name of this object will be a Python package name. Keys in this dict are virtual filenames. Values are raw file data.
- in\_memory\_shared\_library bytes or None holding a shared library that should be imported from memory.
- shared\_library\_dependency\_names list[str] or None holding the names of shared libraries that this
  resource depends on. If this resource defines a loadable shared library, this list can be used to express what other
  shared libraries it depends on.
- relative\_path\_module\_source pathlib.Path or None holding the relative path to Python module
   source that should be imported from the filesystem.
- relative\_path\_module\_bytecode\_opt1 pathlib.Path or None holding the relative path to Python
  module bytecode at optimization level 1 that should be imported from the filesystem.
- relative\_path\_module\_bytecode\_opt1 pathlib.Path or None holding the relative path to Python
   module bytecode at optimization level 2 that should be imported from the filesystem.
- relative\_path\_extension\_module\_shared\_library pathlib.Path or None holding the relative path to a Python extension module that should be imported from the filesystem.
- relative\_path\_package\_resources dict[str, pathlib.Path] or None holding resource files to make available to the importlib.resources APIs via filesystem access. The name of this object will be a Python package name. Keys in this dict are filenames under that package. Values are relative paths to files from which to read data.
- relative\_path\_distribution\_resources dict[str, pathlib.Path] or None holding resource files to make available to the importlib.metadata APIs via filesystem access. The name of this object will be a Python package name. Keys in this dict are filenames under that package. Values are relative paths to files from which to read data.

#### OxidizedResource Resource Types

Each OxidizedResource instance describes a particular type of resource. If a resource identifies as a type, it sets one of the following is\_\* attributes to True:

**is\_module** A Python module. These typically have source or bytecode attached.

Modules can also be packages. In this case, they can hold additional data, such as a mapping of resource files.

- **is\_builtin\_extension\_module** A built-in extension module. These represent Python extension modules that are compiled into the application and don't exist as separate shared libraries.
- **is\_frozen\_module** A frozen Python module. These are Python modules whose bytecode is compiled into the application.
- **is\_extension\_module** A Python extension module. These are shared libraries that can be loaded to provide additional modules to Python.
- is\_shared\_library A shared library. e.g. a . so or .dll.

### 6.5.2 PythonModuleSource

The oxidized\_importer.PythonModuleSource type represents Python module source code. e.g. a .py file.

Instances have the following properties:

module (str) The fully qualified Python module name. e.g. my\_package.foo.

**source** (bytes) The source code of the Python module.

Note that source code is stored as bytes, not str. Most Python source is stored as utf-8, so you can .encode ("utf-8") or .decode ("utf-8") to convert between bytes and str.

**is\_package** (**bool**) This this module is a Python package.

#### 6.5.3 PythonModuleBytecode

The oxidized\_importer.PythonModuleBytecode type represents Python module bytecode. e.g. what a .pyc file holds (but without the header that a .pyc file has).

Instances have the following properties:

module (str) The fully qualified Python module name.

**bytecode** (**bytes**) The bytecode of the Python module.

This is what you would get by compiling Python source code via something like marshal. dumps(compile(source, "exe")). The bytecode does not contain a header, like what would be found in a .pyc file.

**optimize\_level** (int) The bytecode optimization level. Either 0, 1, or 2.

**is\_package** (**bool**) Whether this module is a Python package.

#### 6.5.4 PythonExtensionModule

The oxidized\_importer.PythonExtensionModule type represents a Python extension module. This is a shared library defining a Python extension implemented in native machine code that can be loaded into a process and defines a Python module. Extension modules are typically defined by .so, .dylib, or .pyd files.

Instances have the following properties:

**name** (**str**) The name of the extension module.

Note: Properties of this type are read-only.

#### 6.5.5 PythonPackageResource

The oxidized\_importer.PythonPackageResource type represents a non-module *resource* file. These are files that live next to Python modules that are typically accessed via the APIs in importlib.resources.

Instances have the following properties:

package (str) The name of the leaf-most Python package this resource is associated with.

With OxidizedFinder, an importlib.abc.ResourceReader associated with this package will be used to load the resource.

- name (str) The name of the resource within its package. This is typically the filename of the resource. e.g.
  resource.txt or child/foo.png.
- data (bytes) The raw binary content of the resource.

#### 6.5.6 PythonPackageDistributionResource

The oxidized\_importer.PythonPackageDistributionResource type represents a non-module *re-source* file living in a package distribution directory (e.g. <package>-<version>.dist-info or <package>-<version>.egg-info). These resources are typically accessed via the APIs in importlib. metadata.

Instances have the following properties:

**package** (**str**) The name of the Python package this resource is associated with.

version (str) Version string of Python package this resource is associated with.

**name** (str) The name of the resource within the metadata distribution. This is typically the filename of the resource. e.g. METADATA.

data (bytes) The raw binary content of the resource.

# 6.6 Resource Scanning APIs

The oxidized\_importer module exposes functions and Python types to facilitate scanning for and collecting Python resources.

#### 6.6.1 find\_resources\_in\_path(path)

The oxidized\_importer.find\_resources\_in\_path() function will scan the specified filesystem path and return an iterable of objects representing found resources. Those objects will be 1 of the types documented in *oxidized\_importer Python Resource Types*.

Only directories can be scanned.

To discover all filesystem based resources that Python's PathFinder *meta path finder* would (with the exception of .zip files), try the following:

```
import os
import oxidized_importer
import sys
resources = []
for path in sys.path:
    if os.path.isdir(path):
        resources.extend(oxidized_importer.find_resources_in_path(path))
```

#### 6.6.2 OxidizedResourceCollector Python Type

The oxidized\_importer.OxidizedResourceCollector type provides functionality for turning instances of Python resource types into a collection of OxidizedResource for loading into an OxidizedFinder instance. It exists as a convenience, as working with individual OxidizedResource instances can be rather cumbersome.

Instances can be constructed by passing an allowed\_locations=<list[str]> argument defining locations that resources can be loaded from. The string values are the same as recognized by PyOxidizer's config files and are documented at *Customizing Default Resource Locations*.

e.g. to create a collector that only marks resources for in-memory loading:

```
import oxidized_importer
collector = oxidized_importer.OxidizedResourceCollector(
    allowed_locations=["in-memory"]
)
```

Instances of OxidizedResourceCollector have the following properties:

allowed\_locations (list[str]) Exposes allowed locations where resources can be loaded from.

Methods are documented in the following sections.

#### add\_in\_memory(resource)

OxidizedResourceCollector.add\_in\_memory(resource) adds a Python resource type (PythonModuleSource, PythonModuleBytecode, etc) to the collector and marks it for loading via in-memory mechanisms.

#### add\_filesystem\_relative(prefix, resource)

OxidizedResourceCollector.add\_filesystem\_relative(prefix, resource) adds a Python resource type(PythonModuleSource, PythonModuleBytecode, etc) to the collector and marks it for loading via a relative path next to some *origin* path (as specified to the OxidizedFinder). That relative path can have a prefix value prepended to it. If no prefix is desired and you want the resource placed next to the *origin*, use an empty str for prefix.

#### oxidize()

OxidizedResourceCollector.oxidize() takes all the resources collected so far and turns them into data structures to facilitate later use.

The return value is a tuple of (List[OxidizedResource], List[Tuple[pathlib.Path, bytes, bool]]).

The first element in the tuple is a list of OxidizedResource instances.

The second is a list of 3-tuples containing the relative filesystem path for a file, the content to write to that path, and whether the file should be marked as executable.

# 6.7 Loading Resource Files

Many Python application need to load *resources*. *Resources* are typically non-Python *support* files, such as images, config files, etc. In some cases, *resources* could be Python source or bytecode files. For example, many plugin systems load Python modules outside the context of the normal import mechanism and therefore treat standalone Python source/bytecode files as non-module *resources*.

oxidized\_importer has support for loading resource files. But compatibility with Python's expected behavior may vary.

### 6.7.1 Python Resource Loading Mechanisms

Before we talk about oxidized\_importer's support for resource loading, it is important to understand how Python code in the wild can load resources.

We'll overview them in the chronological order they were introduced into the Python ecosystem.

The most basic and oldest mechanism to load resources is to perform raw filesystem I/O. Typically, Python code looks at \_\_\_\_\_\_file\_\_\_ to get the filename of the current module. Then, it calculates the directory name and derives paths to resource files using e.g. os.path.join(). It will usually then open() these paths directly.

Python packaging evolved over time. Packaging tools could express various metadata at build time, such as supplementary *resource* files. This metadata would be installed next to a package and APIs could be used to access it. One such API was pkg\_resources. Using e.g. pkg\_resources.resource\_string("foo", "bar.txt"), you could obtain the content of the resource bar.txt in the foo package.

pkg\_resources had useful functionality. And it was the recommended mechanism for loading resource files for several years. But it wasn't part of the Python standard library and needed to be explicitly installed. So not everyone used it.

Python 3.1 added the importlib package, which is the primary home for all core functionality related to import. Python importers were now defined via interfaces. One of those interfaces is ResourceLoader. It has a single method get\_data(path). Given a Python module's loader (e.g. via the \_\_loader\_\_ attribute on the module), you could call get\_data(path) and load a resource. e.g. import foo; foo.\_\_loader\_\_. get\_data("bar.txt").

The standard library only had ResourceLoader for several years. And ResourceLoader wasn't exactly a convenient API to use because it was so low-level. Many Python applications continued to use pkg\_resources or direct file-based I/O.

Python 3.7 introduced significant improvements to resource loading in the standard library.

At a low level, module loaders could now implement a get\_resource\_reader(name) method, which would return an object implementing the ResourceReader interface. This interface defined methods like open\_resource(name) and contents() to open a file-like handle on a named resource and obtain a list of all available resources.

At a high level, the importlib.resources package provided a user-friendly API for interacting with ResourceReader instances. You could call e.g. importlib.resources.open\_binary (package, name) to obtain a file-like handle on a specific resource within a package.

Python 3.7's new resource APIs finally gave the Python standard library access to powerful APIs for loading resources without using a 3rd party package (like pkg\_resources).

At the time of writing this in April 2020, it looks like Python 3.9 will invent yet another low-level resource loading API.

**Important:** As of Python 3.8, ResourceReader and importlib.resources are the most robust mechanisms for loading resources and we recommend adopting these APIs if possible.

### 6.7.2 Support for ResourceReader

oxidized\_importer implements the ResourceReader interface for loading resource files.

However, compatibility with Python's default filesystem-based implementation can vary. Unfortunately, various behavior with ResourceReader is undefined, so it isn't clear if CPython or oxidized\_importer is buggy here.

oxidized\_importer maintains an index of known resource files. This index is logically a dict of dict``s, where the outer key is the Python package name and the inner key is the resource name. Package names are fully qualified. e.g. ``foo or foo.bar. Resource names are effectively relative filesystem paths. e.g. resource.txt or subdir/resource.txt. The relative paths always use / as the directory separator, even on Windows.

OxidizedFinder.get\_resource\_reader() returns instances of OxidizedResourceReader. Each instance is bound to a specific Python package: that's how they are defined. When an OxidizedResourceReader receives the name of a resource, it performs a simple lookup in the global resources index. If the string key is found, it is used. Otherwise, it is assumed the resource doesn't exist.

The OxidizedResourceReader.contents() method will return a list of all keys in the internal resources index.

OxidizedResourceReader works the same way for in-memory and filesystem-relative *Resource Locations* because internally both use the same index of resources to drive execution: only the location of the resource content varies.

OxidizedResourceReader's implementation varies from the standard library filesystem-based implementation in the following ways:

- OxidizedResourceReader.contents() will return keys from the package's resources dictionary, not all the files in the same directory as the underlying Python package (the standard library uses os.listdir()). OxidizedResourceReader will therefore return resource names in sub-directories as long as those sub-directories aren't themselves Python packages.
- Resources must be explicitly registered with OxidizedFinder as such in order to be exposed via the resources API. By contrast, the filesystem-based importer relying on os.listdir() will expose all files in a directory as a resource. This includes .py files.
- OxidizedResourceReader.is\_resource() will return True for resource names containing a slash. Contrast with Python's, which returns False (even though you can open a resource with ResourceReader. open\_resource() for the same path). OxidizedResourceReader's behavior is more consistent.

# 6.7.3 Support for ResourceLoader

OxidizedFinder implements the deprecated ResourceLoader interface and get\_data(path) will return bytes instances for registered resources or raise OSError on request of an unregistered resource.

The path passed to get\_data (path) MUST be an absolute path that has the prefix of either the currently running executable file or the directory containing it.

If the resource path is prefixed with the current executable's path, the path components after the current executable path are interpreted as the path to a resource registered for in-memory loading.

If the resource path is prefixed with the current executable's directory, the path components after this directory are interpreted as the path to a resource registered for application-relative loading.

All other resource paths aren't recognized and an OSError will be raised. There is no fallback to loading from the filesystem, even if a valid filesystem path pointing to an existing file is passed in.

**Note:** The behavior of not servicing paths that actually exist but aren't registered with OxidizedFinder as resources may be overly opinionated and undesirable for some applications.

If this is a legitimate use case for your application, please create a GitHub issue to request this feature.

Once a path is recognized as having the prefix of the current executable or its directory, the remaining path components will be interpreted as the resource path. This resource path logically contains a package name component and a resource name component. OxidizedFinder will traverse all potential package names starting from the longest/deepest up until the top-level package looking for a known Python package. Once a known package name is encountered, its resources will be consulted. At most 1 package will be consulted for resources.

Here is a concrete example.

If the path is /usr/bin/myapp/foo/bar/resource.txt and the current executable is /usr/bin/myapp, the requested resource will be foo/bar/resource.txt. Since the path was prefixed with the executable path, only resources registered for in-memory loading will be consulted.

Our candidate package names are foo.bar and foo, in that order.

If foo.bar is a known package and resource.txt is registered for in-memory loading, that resource's contents will be returned.

If foo.bar is a known package and resource.txt is not registered in that package, OSError is raised.

If foo.bar is not a known package, we proceed to check for package foo.

If foo is a known package and bar/resource.txt is registered for in-memory loading, its contents will be returned.

Otherwise, we're out of possible packages, so OSError is raised.

Similar logic holds for resources registered for filesystem-relative loading. The difference here is the stripped path prefix and we are only looking for resources registered for filesystem-relative loading. Otherwise, the traversal logic is exactly the same.

If OSError is raised due to a missing resource, its errno is ENOENT and its filename is the passed in path. Python should automatically translate this to a FileNotFoundError exception. But callers should catch OSError, as other OSError variants can be raised (e.g. for file permission errors).

# 6.7.4 Support for \_\_\_\_\_file\_\_\_

OxidizedFinder may or may not set the \_\_\_\_\_\_file\_\_\_ attribute on loaded modules. See \_\_\_\_\_\_file\_\_ and \_\_\_\_\_cached\_\_\_\_ Module Attributes for details. Therefore, Python code relying on the presence of \_\_\_\_\_\_\_\_ to derive paths to resource files may or may not work with oxidized\_importer.

Code utilizing \_\_\_\_\_\_\_file\_\_\_\_ for resource loading is highly encouraged to switch to the importlib.resources API. If this is not possible, you can change packaging settings to move the *Resource Locations* from in-memory to filesystem-relative, as \_\_\_\_\_\_\_file\_\_\_\_ is set when loading modules from the filesystem.

#### 6.7.5 Support for pkg\_resources

pkg\_resources's APIs for loading resources likely do not work with oxidized\_importer.

### 6.7.6 Porting Code to Modern Resources APIs

Say you have resources next to a Python module. Legacy code *inside a module* might do something like the following:

```
def get_resource(name):
    """Return a file handle on a named resource next to this module."""
    module_dir = os.path.abspath(os.path.dirname(__file__))
    # Warning: there is a path traversal attack possible here if
    # name continues values like ../../../etc/password.
    resource_path = os.path.join(module_dir, name)
```

return open(resource\_path, 'rb')

Modern code targeting Python 3.7+ can use the ResourceReader API directly:

```
def get_resource(name):
    """Return a file handle on a named resource next to this module."""
    # get_resource_reader() may not exist or may return None, which this
    # code doesn't handle.
    reader = __loader__.get_resource_reader(__name__)
    return reader.open_resource(name)
```

The ResourceReader interface is quite low-level. If you want something higher level or want to access resources outside the current module, it is recommended to use the importlib.resources APIs. e.g.:

import importlib.resources
with importlib.resources.open\_binary('mypackage', 'resource-name') as fh:
 data = fh.read()

The importlib.resources functions are glorified wrappers around the low-level interfaces on module loaders. But they do provide some useful functionality, such as additional error checking and automatic importing of modules, making them useful in many scenarios, especially when loading resources outside the current package/module.

### 6.7.7 Maintaining Compatibility With Python <3.7

If you want to maintain compatibility with Python <3.7, you can't use ResourceReader or importlib. resources, as they are not available. The recommended solution here is to use a shim.

The best shim to use is importlib\_resources. This is a standalone Python package that is a backport of importlib. resources to older Python versions. Essentially, you can always get the APIs from the latest Python version. This shim knows about the various APIs available on Loader instances and chooses the best available one. It should *just work* with oxidized\_importer.

If you want to implement your own shim without introducing a dependency on importlib\_resources, the following code can be used as a starting implementation:

```
import importlib
try:
    import importlib.resources
    # Defeat lazy module importers.
    importlib.resources.open_binary
   HAVE_RESOURCE_READER = True
except ImportError:
   HAVE_RESOURCE_READER = False
try:
    import pkg_resources
    # Defeat lazy module importers.
   pkg_resources.resource_stream
    HAVE_PKG_RESOURCES = True
except ImportError:
   HAVE_PKG_RESOURCES = False
def get_resource(package, resource):
    """Return a file handle on a named resource in a Package."""
    # Prefer ResourceReader APIs, as they are newest.
    if HAVE_RESOURCE_READER:
        # If we're in the context of a module, we could also use
        # ``
            __loader__.get_resource_reader(__name__).open_resource(resource)``.
        # We use open_binary() because it is simple.
        return importlib.resources.open_binary(package, resource)
    # Fall back to pkg_resources.
    if HAVE_PKG_RESOURCES:
        return pkg_resources.resource_stream(package, resource)
    # Fall back to _____file___.
    # We need to first import the package so we can find its location.
    # This could raise an exception!
    mod = importlib.import_module(package)
    # Undefined _____file___ will raise NameError on variable access.
   try:
        package_path = os.path.abspath(os.path.dirname(mod.__file__))
    except NameError:
        package_path = None
    if package_path is not None:
        # Warning: there is a path traversal attack possible here if
        # resource contains values like ../../../etc/password. Input
        # must be trusted or sanitized before blindly opening files or
        # you may have a security vulnerability!
        resource_path = os.path.join(package_path, resource)
        return open(resource_path, 'rb')
    # Could not resolve package path from _____file___.
```

(The above code is dedicated to the public domain and can be used without attribution.)

This code is provided for example purposes only. It may or may not be sufficient for your needs.

### 6.8 Freezing Applications with oxidized\_importer

oxidized\_importer can be used to create and run *frozen* Python applications, where Python resources data (module source and bytecode, etc) is *frozen*/packaged and distributed next to your *application*.

This is conceptually similar to what PyOxidizer does. The major difference is that PyOxidizer will package and distribute a Python distribution with your application: when only oxidized\_importer is being used, the Python distribution is provided by some other means (it is typically already installed on the system). This makes oxidized\_importer a light-weight alternative to PyOxidizer for scenarios where PyOxidizer isn't suitable or viable.

#### 6.8.1 High-Level Freezing Workflow

The steps for *freezing* an application all look the same:

- 1. Load OxidizedResource instances into an OxidizedFinder instance so they are indexed.
- 2. Serialize indexed resources.
- 3. Write the serialized resources blob somewhere along with any files (if using filesystem-based loading).
- 4. Somehow make that resources blob available to others (you could add it as a *resource* file in your Python package for example).
- 5. From your application, construct an OxidizedFinder instance and load the resources blob you generated.
- 6. Register the OxidizedFinder instance as the first element on sys.meta\_path.

The next sections show what this may look like.

#### 6.8.2 Indexing and Serializing Resources

In your *build* process, you'll need to index resources and serialize them. You can construct OxidizedResource instances directly and hand them off to an OxidizedFinder instance. But you'll probably want to use OxidizedResourceCollector to make this simpler.

Try something like the following:

```
# Add all known Python resources by scanning sys.path.
# Note: this will pull in the Python standard library and
# any other installed packages, which may not be desirable!
for path in sys.path:
    # Only directories can be scanned by oxidized_importer.
    if os.path.isdir(path):
        for resource in oxidized importer.find resources_in_path(path):
            collector.add_in_memory(resource)
# Turn the collected resources into ``OxidizedResource`` and file
# install rules.
resources, file_installs = collector.oxidize()
# Now index the resources so we can serialize them.
finder = oxidized_importer.OxidizedFinder()
finder.add_resources(resources)
# Turn the indexed resources into an opaque blob.
packed_data = finder.serialize_indexed_resources()
# Write out that data somewhere.
with open("oxidized_resources", "wb") as fh:
    fh.write(packed_data)
# Then for all the file installs, materialize those files.
for (path, data, executable) in file_installs:
   path.parent.mkdir(parents=True, exist_ok=True)
   with path.open("wb") as fh:
        fh.write(data)
    if executable:
        path.chmod(path.stat().st_mode | stat.S_IEXEC)
```

At this point, you've collected all known Python resources and written out a data structure describing them all. For resources targeting in-memory loading, the content of those resources is embedded in the data structure. For resources targeting filesystem-relative loading, the data structure contains the relative path to those resources. And you've written out the files in the locations where those relative paths point to.

#### 6.8.3 Loading Serialized Resources in Your Application

Now, from our *application* code, we need to load the resources and register the custom importer with Python:

```
import os
import sys
import oxidized_importer
# Load those resources into an instance of our custom importer. This
# will read the index in the passed data structure and make all
# resources immediately available for importing.
finder = oxidized_importer.OxidizedFinder(resources_file="oxidized_resources")
# If the relative path of filesystem-based resources is not relative
```

```
# to the current executable (which is likely the ``python3`` executable),
# you'll need to set ``origin`` to the directory the resources are
# relative to.
finder = oxidized_importer.OxidizedFinder(
    resources=packed_data,
    relative_path_origin=os.path.dirname(os.path.abspath(__file__)),
)
# Register the meta path finder as the first item, making it the
# first finder that is consulted.
sys.meta_path.insert(0, finder)
# At this point, you should be able to ``import`` modules defined
# in the resources data!
```

### 6.9 Common Issues

#### 6.9.1 Extension Modules Support

Unlike PyOxidizer, OxidizedResourceCollector isn't (yet) as intelligent about how to handle extension modules (standalone machine native shared libraries). And even PyOxidizer's support for extension modules can be brittle.

One notable difference between PyOxidizer and OxidizedResourceCollector is PyOxidizer is able to determine whether importing extension modules from memory is supported and is able to automatically redirect an extension module to filesystem-based loading if not supported. OxidizedResourceCollector is *dumb* and adds resources where you tell it to.

OxidizedFinder supports loading extension modules from memory on Windows. But everywhere else, this isn't supported and will result in an ImportError if you index an extension module for in-memory loading.

To work around this deficiency, you'll want to mark extension modules as loaded from the filesystem unless you are on Windows. Try something like this:

```
import oxidized_importer
collector = oxidized_importer.OxidizedResourceCollector(
    allowed_locations=["in-memory", "filesystem-relative"],
)
# Redirect extension modules to the filesystem and everything else to
# memory.
for resource in oxidized_importer(find_resources_in_path("/path/to/resources")):
    if isinstance(resource, oxidized_importer.PythonExtensionModule):
        collector.add_filesystem_relative("lib", resource)
else:
        collector.add_in_memory(resource)
```

#### 6.9.2 Resource Scanning Descends Into site-packages

oxidized\_importer.find\_resources\_in\_path() descends into site-packages directories. This is arguably not the desired behavior, especially when in the context of virtualenvs, which may want to not inherit the resources in the site-packages of the *outer* Python installation. This will likely be fixed in a future release.

# 6.10 Security Implications of Loading Resources

OxidizedFinder allows Python code to define its own OxidizedResource instances to be made available for loading. This means Python code can define its own Python module source or bytecode that could later be executed. It also allows registration of extension modules and shared libraries, which give a vector for allowing execution of native machine code.

This feature has security implications, as it provides a vector for arbitrary code execution.

While it might be possible to restrict this feature to provide stronger security protections, we have not done so yet. Our thinking here is that it is extremely difficult to sandbox Python code. Security sandboxing at the Python layer is effectively impossible: the only effective mechanism to sandbox Python is to add protections at the process level. e.g. by restricting what system calls can be performed. We feel that the capability to inject new Python modules and even shared libraries via OxidizedFinder doesn't provide any new or novel vector that doesn't already exist in Python's standard library and can't already be exploited by well-crafted Python code. Therefore, this feature isn't a net regression in security protection.

If you have a use case that requires limiting the features of OxidizedFinder so security isn't sacrificed, please *file an issue <https://github.com/indygreg/PyOxidizer/issues>*.

# CHAPTER 7

### Python Packed Resources

PyOxidizer has defined a custom data format for storing resources useful to the execution of a Python interpreter. We call this data format *Python packed resources*.

The way it works is that some producer collects resources required by a Python interpreter. These resources include Python module source and bytecode, non-module resource/data files, extension modules, and shared libraries. Meta-data about these resources and sometimes the raw resource data itself is serialized to a binary data structure.

At Python interpreter run time, this data structure is loaded (it can be embedded in a binary or exist as a standalone file) and parsed. A custom *Python Meta Path Finders (OxidizedFinder* from *oxidized\_importer Python Extension)* then uses the parsed data structure to power Python module importing.

This functionality is similar to using a .zip file for holding Python modules. However, the *Python packed resources* data structure is far more advanced.

### 7.1 Implementation

The canonical implementation of the writer and parser of this data structure lives in the python-packed-resources Rust crate. The canonical home of this crate is https://github.com/indygreg/ PyOxidizer/tree/main/python-packed-resources.

This crate is published to crates.io at https://crates.io/crates/python-packed-resources.

# 7.2 Specification

From a high level, the data structure defines an iterable of *resources*. A *resource* is an entity with a name, metadata, and blob fields. Typically the most common *resource* is a Python module/package. But other resource types (such as shared libraries) are defined.

The first 8 bytes of the data structure are a magic header identifying the content as our data structure and the version of it. The first 7 bytes are pyembed and the following 1 byte denotes a version. Semantics of each version are denoted in sections below.

### 7.2.1 High-Level Layout

From a high-level, the serialized format consists of:

- A global header describing the overall payload.
- An index describing the blob sections present in the payload.
- An index describing each resource and its content.
- A series of blob sections holding the data referenced by the resources index.

A resource is composed of various *fields* that describe it. Examples of fields include the resource name, source code, and bytecode. The resources index describes which fields are present and where to find them in the payload.

The actual content of fields (e.g. the raw bytes containing source code) is stored in field-specific sections after the index. Each field has its own section and data for all resources is stored next to each other. e.g. you will have all the data for resource names followed by all data for module sourcecode.

The low-level data format is described below. All integers are little-endian.

The first 13 bytes after the magic header denote a global header. The global header consists of:

- A u8 denoting the number of blob sections, blob\_sections\_count.
- A u32 denoting the length of the blob index, blob\_index\_length.
- A u32 denoting the total number of resources in this data, resources\_count.
- A u32 denoting the length of the resources index, resources\_index\_length.

Following the *global header* is the *blob index*. The blob index describes the various blob sections present in the payload following the *resources index*.

Each entry in the *blob index* logically consists of a set of fields defining metadata about each *blob section*. This is encoded by a *start of entry* u8 marker followed by N u8 field type values and their corresponding metadata, followed by an *end of entry* u8 marker. The *blob index* is terminated by an *end of index* u8 marker. The total number of bytes in the *blob index* including the *end of index* marker should be blob\_index\_length.

Following the *blob index* is the *resources index*. Each entry in this index defines a sparse set of metadata describing a single resource. Entries are composed of a series of u8 identifying pieces of metadata, followed by field-specific supplementary descriptions. For example, a value of  $0 \times 02$  denotes the length of the resources's name and is immediately followed by a u16 holding said length. See the section below for each field tracked by this index.

Following the *resources index* is blob data. Blob data is logically consisted of different sections holding data for different fields for different resources. But there is no internal structure or separators: all the individual blobs are just laid out next to each other.

### 7.2.2 Blob Field Types

The Blob Index allows attributing a sparse set of metadata with every blob section entry. The type of metadata being conveyed is defined by a u8. Some field types have additional metadata following that field.

The various field types and their semantics follow.

- **0x00** End of index. This field indicates that there are no more blob index entries and we've reached the end of the *blob index*.
- **0x01** Start of blob section entry. Encountering this value signals the beginning of a new blob section. From a specification standpoint, this isn't strictly required. But it helps ensure parser state.
- **0xff** End of blob section entry. Encountering this value signals the end of the current blob section definition. The next encountered u8 in the index should be  $0 \times 01$  to denote a new entry or  $0 \times 00$  to denote end of index.

- **0x02** Resource field type. This field defines which resource field this blob section is holding data for. A u8 following this one will contain the resource field type value (see section below).
- **0x03** Raw payload length. This field defines the raw length in bytes of the blob section in the payload. The u64 containing that length will immediately follow this u8.
- **0x04** Interior padding mechanism. This field defines interior padding between elements in the blob section. Following this u8 is another u8 denoting the padding mechanism.

 $0 \times 01$  indicates no padding.  $0 \times 02$  indicates NULL padding (a  $0 \times 00$  between elements).

If not present, *no padding* is assumed. If the payload data logically consists of discrete resources (e.g. Python package resource files), then padding applies to these sub-elements as well.

#### 7.2.3 Resource Field Types

The Resources Index allows attributing a sparse set of metadata with every resource. A u8 indicates what metadata is being conveyed. Some field types have additional metadata following this [u8] further defining the field. The values of each defined metadata type follow.

- **0x00** End of index. Special type to denote the end of an index.
- **0x01** Start of resource entry. Signals the beginning of a new resource. From a specification standpoint this isn't strictly required. But it helps ensure parser state.
- **0x02** Resource flavor. Declares the type of resource this entry represents. A u8 defining the resource flavor immediately follows this byte. See the section below for valid resource flavors.

This field is deprecated in version 2 in favor of the individual fields expressing presence of a resource type. (See fields starting at  $0 \times 16$ .)

- **0xff** End of resource entry. The next encountered u8 in the index should be an *end of index* or *start of resource* marker.
- **0x03** Resource name. A u16 denoting the length in bytes of the resource name immediately follows this byte. The resource name *must* be valid UTF-8.
- **0x04** Package flag. If encountered, the resource is identified as a Python package.
- **0x05** Namespace package flag. If encountered, the resource is identified as a Python *namespace package*.
- **0x06** In-memory Python module source code. A u32 denoting the length in bytes of the module's source code immediately follows this byte.
- **0x07** In-memory Python module bytecode. A u32 denoting the length in bytes of the module's bytecode immediately follows this byte.
- **0x08** In-memory Python module optimized level 1 bytecode. A u32 denoting the length in bytes of the module's optimization level 1 bytecode immediately follows this byte.
- **0x09** In-memory Python module optimized level 2 bytecode. Same as previous, except for bytecode optimization level 2.
- **0x0a** In-memory Python extension module shared library. A u32 denoting the length in bytes of the extension module's machine code immediately follows this byte.
- **0x0b** In-memory Python resources data. If encountered, the module/package contains non-module resources files and the number of resources is contained in a u32 that immediately follows. Following this u32 is an array of (u16, u64) denoting the resource name and payload size for each resource in this package.
- **OxOc** In-memory Python distribution resource. Defines resources accessed from importlib.metadata APIs. If encountered, the module/package contains distribution metadata describing the package. The number of files

being described is contained in a u32 that immediately follows this byte. Following this u32 is an array of (u16, u64) denoting the distribution file name and payload size for each virtual file in this distribution.

- **0x0d** In-memory shared library. If set, this resource is a shared library and not a Python module. The resource name field is the name of this shared library, with file extension (as it would appear in a dynamic binary's loader metadata to indicate a library dependency). A u64 denoting the length in bytes of the shared library data follows. This shared library should be loaded from memory.
- **0x0e** Shared library dependency names. This field indicates the names of shared libraries that this entity depends on. The number of library names is contained in a u16 that immediately follows this byte. Following this u16 is an array of u16 denoting the length of the library name for each shared library dependency. Each described shared library dependency may or may not be described by other entries in this data structure.
- **0x0f** Relative filesystem path to Python module source code. A u32 holding the length in bytes of a filesystem path encoded in the platform-native file path encoding follows. The source code for a Python module will be read from a file at this path.
- **0x10** Relative filesystem path to Python module bytecode. Similar to the previous except the filesystem path holds Python module bytecode.
- **0x11** Relative filesystem path to Python module bytecode at optimization level 1. Similar to the previous except for what is being pointed to.
- **0x12** Relative filesystem path to Python module bytecode at optimization level 2. Similar to the previous except for what is being pointed to.
- **0x13** Relative filesystem path to Python extension module shared library. Similar to the previous except the file holds a Python extension module loadable as a shared library.
- **0x14** Relative filesystem path to Python package resources. The number of resources is contained in a u32 that immediately follows. Following this u32 is an array of (u16, u32) denoting the resource name and filesystem path to each resource in this package.
- **0x15** Relative filesystem path to Python distribution resources.

Defines resources accessed from importlib.metadata APIs. If encountered, the module/package contains distribution metadata describing the package. The number of files being described is contained in a u32 that immediately follows this byte. Following this u32 is an array of (u16, u32) denoting the distribution file name and filesystem path to that distribution file.

- **0x16** Is Python module flag. If set, this resource contains data for an importable Python module or package. Resource data is associated with Python packages and is covered by this type.
- **0x17** Is built extension module flag. This type represents a Python extension module that is built in (compiled into) the interpreter itself or is otherwise made available to the interpreter via PyImport\_Inittab such that it should be imported with the *builtin* importer.
- **0x18** Is frozen Python module flag. This type represents a Python module whose bytecode is *frozen* and made available to the Python interpreter via the PyImport\_FrozenModules array and should be imported with the *frozen* importer.
- **0x19** Is Python extension flag. This type represents a compiled Python extension. Extensions have specific requirements around how they are to be loaded and are differentiated from regular Python modules.
- **0x1a** Is shared library flag. This type represents a shared library that can be loaded into a process.
- **0x1b** Is utf-8 filename data flag. This type represents an arbitrary filename. The resource name is a UTF-8 encoded filename of the file this resource represents. The file's data is either embedded in memory or referred to via a relative path reference.
- **0x1c** File data is executable flag.

If set, the arbitrary file this resource tracks should be marked as executable.

**0x1d** Embedded file data.

If present, the resource should be a file resource and this field holds its raw file data in memory.

A u64 containing the length of the embedded data follows this field.

**0x1e** UTF-8 relative path file data.

If present, the resource should be a file resource and this field defines the relative path containing that file's data. The relative path filename is UTF-8 encoded.

A u32 denoting the length of the UTF-8 relative path (in bytes) follows.

#### 7.2.4 Resource Flavors

**Important:** Enumerated resource flavors are deprecated after version 1. You should use individual fields to express resource identity instead.

The data format allows defining different types/flavors of resources. This flavor of a resource is identified by a u8. The declared flavors are:

**0x00** No flavor. Should not be encountered.

**0x01** Python module/package. This is equivalent to resource field 0x16 being set.

 $0 \times 02$  Builtin Python extension module. This is equivalent to resource field  $0 \times 17$  being set.

**0x03** Frozen Python module. This is equivalent to resource field 0x18 being set.

 $0 \times 04$  Python extension. This is equivalent to resource field  $0 \times 19$  being set.

**0x05** Shared library. This is equivalent to resource field 0x1a being set.

#### 7.2.5 pyembed\x01 Format

The initially released/formalized packed resources data format.

Supports resource field types up to and including 0x15.

#### 7.2.6 pyembed\x02 Format

Version 2 of the packed resources data format.

This version introduces field type values  $0 \times 16$  to  $0 \times 1a$ . The resource flavor field type  $(0 \times 02)$  is deprecated and the individual field types denoting resource types should be used instead.

(PyOxidizer removed run-time code looking at field type 0x02 when this format was introduced.)

#### 7.2.7 pyembed\x03 Format

Version 3 of the packed resources data format.

This version introduces field type values 0x1b to 0x1e.

These fields provide the ability for a resource to identify itself as an arbitrary filename and for the arbitrary file data to be embedded within the data structure or referenced via a relative path.

Unlike previous fields that use OS-native encoding of filesystem paths ([u8] on POSIX and [u16] on Windows), the paths for these new fields use UTF-8. This can't represent all valid paths on all platforms. But it is portable and works for most paths encountered in the wild.

# 7.3 Design Considerations

The design of the packed resources data format was influenced by a handful of considerations.

Performance is a significant consideration. We want everything to be as fast as possible. Possible dimensions influencing performance include parse time, payload size, and I/O access patterns.

The payload is designed such that the *index* data is at the beginning so a reader only has to read a contiguous slice of data to fully understand the data within. This is in opposition to jumping around the entire data structure to extract metadata of the data within. This means that we only need to page in a fraction of the total backing data structure in order to initialize our custom importer. In addition, the index data is read sequentially. Sequential I/O should always be faster than random access I/O.

x86 is little endian, so we use little endian integers so we don't need to waste cycles on endian transformation.

We store all data for the same field next to each other in the data structure. This is in opposition to say packing all of resource A's data then resource B's, etc. We do this to help maximize locality for similar data. This can help with performance because often the same field for multiple resources is accessed together. e.g. an importer will access a bunch of module bytecode entries at the same time. This locality helps minimize the number of pages that must be read. Locality can also help yield higher compression ratios.

Everything is designed to facilitate a reader leveraging 0-copy. If a reader has the data structure in memory, we don't want to require it to copy memory in order to reference entries. In Rust speak, we should be able to hold & [u8] references everywhere.

There is no checksumming of the data because we don't want to incur I/O overhead to read the entire blob. It could be added as an optional feature.

# 7.4 Potential Future Features

This data structure is robust enough to be used by PyOxidizer to power importing of every Python module used by a Python interpreter. However, there are various aspects that could be improved.

### 7.4.1 Compression

A potential area for optimization is use of general compression. Various fields should compress well - either in streaming mode or by utilizing compression dictionaries. Compression would undermine 0-copy, of course. But in environments where we want to optimize for size, it could be desirable.

### 7.4.2 Platform Portability

Currently, filesystem paths are encoded as platform native. That means [u8] on POSIX and [u16] on Windows. This isn't portable.

Most filenames are likely ASCII or UTF-8 safe. For the common case where we don't need platform-native filenames to preserve subtle encoding differences, we could express paths as a simpler string type.

# CHAPTER 8

### PyOxidizer for Rust Developers

PyOxidizer is implemented in Rust. Binaries built with PyOxidizer are also built with Rust using standard Rust projects.

While the existence of Rust should be abstracted away from most users (aside from the existence of the install dependency and build output), a target audience of PyOxidizer is Rust developers who want to embed Python in a Rust project or Python developers who want to leverage more Rust in their Python applications.

Follow the links below to learn how PyOxidizer uses Rust and how Rust can be leveraged to build more advanced applications embedding Python.

### 8.1 Using Cargo with PyOxidizer Source Checkouts

PyOxidizer's source repository consists of multiple Rust projects/crates. At the root of the repository is a Cargo. toml defining a workspace consisting of all these crates.

**Important:** Building various Rust crates from source can be extremely brittle and a top-level cargo build will likely encounter multiple build failures.

If you want to run cargo from a PyOxidizer source checkout, you will likely want to limit the invocation to a single crate at a time to ensure things can build.

The following sections detail how to build various crates inside a source checkout.

#### 8.1.1 pyoxidizer Crate

Building the pyoxidizer crate in isolation (e.g. cargo build -p pyoxidizer) should *just work*, as it is a pretty typical Rust crate.

Perhaps the only special property of this crate is that it defines both a library and an executable. So you may want to limit operations to a specific binary. e.g. cargo build --bin pyoxidizer or cargo test --bin pyoxidizer.

#### 8.1.2 python-packed-resources Crate

This is a standard Rust crate and should always build without issue. e.g. cargo build -p python-packed-resources.

#### 8.1.3 python-packaging Crate

This is a standard Rust crate and should always build without issue. e.g. cargo build -p python-packaging or cargo test -p python-packaging.

#### 8.1.4 pyembed Crate

The pyembed crate provides the bulk of the run-time functionality for binaries embedding Python interpreters. Because the crate needs to consult with a Python interpreter at build time and link against it and because it needs to exchange state with PyOxidizer, its build configuration is... *special*.

**Important:** Almost all workspace build failures are somehow related to the pyembed crate.

The pyembed crate defines various features to control how it is built. See Crate Configuration for details.

In its default configuration, a Python 3.8 executable needs to be found on PATH. If said executable can't be found, you'll get a No python interpreter found of version 3.\* error at build time.

To work around this, add a python3.8 or python3 executable to PATH or run cargo build with the PYTHON\_SYS\_EXECUTABLE environment variable pointing to a specific Python 3 executable. e.g.

\$ PYTHON\_SYS\_EXECUTABLE=/path/to/python3.8 cargo build -p pyembed

#### 8.1.5 oxidized-importer Crate

This crate is a very small shim around the pyembed crate which builds the pyembed crate in a specific manner so it provides just the functionality needed for *oxidized\_importer Python Extension*.

Because this crate is a thin shim, the caveats that apply to building pyembed apply to it as well.

### 8.2 Rust Projects

PyOxidizer uses Rust projects to build binaries embedding Python.

If you just have a standalone configuration file (such as when running pyoxidizer init-config-file), a temporary Rust project will be created as part of building binaries. That project will be built, its build artifacts copied, and the temporary project will be deleted.

If you use pyoxidizer init-rust-project to initialize a PyOxidizer application, the Rust project exists side-by-side with the PyOxidizer configuration file and can be modified like any other Rust project.

#### 8.2.1 Layout

Generated Rust projects all have a similar layout:

```
$ find pyapp -type f | grep -v .git
Cargo.toml
build.rs
pyoxidizer.bzl
src/main.rs
```

The Cargo.toml file is the configuration file for the Rust project. Read more in the official Cargo documentation. The magic lines in this file to enable PyOxidizer are the following:

```
[package]
build = "build.rs"
[dependencies]
pyembed = ...
```

These lines declare a dependency on the pyembed package, which holds the smarts for embedding Python in a binary.

In addition, the build = "build.rs" tells runs a script that hooks up the output of the pyembed crate with this project.

Next let's look at src/main.rs. If you aren't familiar with Rust projects, the src/main.rs file is the default location for the source file implementing an executable. If we open that file, we see a fn main() { line, which declares the *main* function for our executable. The file is relatively straightforward. We import some symbols from the pyembed crate. We then construct a config object, use that to construct a Python interpreter, then we run the interpreter and pass its exit code to exit(). Succinctly, we instantiate and run an embedded Python interpreter. That's our executable.

The pyoxidizer.bzl is our auto-generated PyOxidizer configuration file.

### 8.3 Crate Configuration

#### 8.3.1 Build Artifacts for pyembed

The pyembed crate needs to reference special artifacts as part of its build process in order to compile a Python interpreter into a binary. The most important of these artifacts is a library providing Python symbols.

By default, the pyembed crate's build.rs build script will run pyoxidizer run-build-script, which will attempt to find a PyOxidizer config file and evaluate its default *build script* target. Using environment variables set by cargo and by the build.rs script, artifacts will be placed in the correct locations and pyembed will be built seemingly like any normal Rust crate.

The special build artifacts are generated by resolving a configuration file target returning a *PythonEmbeddedResources* instance. In the auto-generated configuration file, the embedded target returns such a type.

### 8.3.2 Cargo Features to Control Building

The pyembed crate and generated Rust projects share a set of build-mode-\* Cargo feature flags to control how build artifacts are created and consumed.

The features are described in the following sections.

#### build-mode-standalone

Do not attempt to invoke pyoxidizer or find artifacts it would have built. It is possible to build the pyembed crate in this mode if the rust-cpython and python3-sys crates can find a Python interpreter. But, the pyembed crate may not be usable or work in the way you want it to.

This mode is intended to be used for performing quick testing on the pyembed crate. It is quite possible that linking errors will occur in this mode unless you take additional actions to point Cargo at appropriate libraries.

#### build-mode-pyoxidizer-exe

A pyoxidizer executable will be run to generate build artifacts.

The path to this executable can be defined via the PYOXIDIZER\_EXE environment variable. Otherwise PATH will be used.

At build time, pyoxidizer run-build-script will be run. A PyOxidizer configuration file will be discovered using the heuristics described at *Automatic File Location Strategy*. OUT\_DIR will be set if running from cargo, so a pyoxidizer.bzl next to the main Rust project being built should be found and used.

pyoxidizer run-build-script will resolve the default build script target by default. To override which target should be resolved, specify the target name via the PYOXIDIZER\_BUILD\_TARGET environment variable. e.g.:

\$ PYOXIDIZER\_BUILD\_TARGET=build-artifacts cargo build

#### build-mode-prebuilt-artifacts

This mode tells the build script to reuse artifacts that were already built. (Perhaps you called pyoxidizer build or pyoxidizer run-build-script outside the context of a normal cargo build.)

In this mode, the build script will look for artifacts in the directory specified by PYOXIDIZER\_ARTIFACT\_DIR if set, falling back to OUT\_DIR. This directory **must** have a cargo\_metadata.txt file, which will be printed to stdout by the build script to tell Cargo how to link a Python library.

#### cpython-link-unresolved-static

Configures the link mode of the cpython crate to use a static pythonXY library without resolving the symbol at its own build time. The pyembed crate or a crate building it will need to emit cargo:rustc-link-lib=static=pythonXY and any cargo:rustc-link-search=native={} lines to specify an explicit pythonXY library to link against.

This is the link mode used to produce self-contained binaries containing libpython and pyembed code.

#### cpython-link-default

Configures the link mode of the cpython crate to use default semantics. The crate's build script will find a prebuilt Python library by querying the python defined by PYTHON\_SYS\_EXECUTABLE or found on PATH. See the cpython crate's documentation for more.

This link mode should be used when linking against an existing libpython that can be found by the cpython crate's build script.

# 8.4 Controlling Python From Rust Code

PyOxidizer can be used to embed Python in a Rust application.

This page documents what that looks like from a Rust code perspective.

### 8.4.1 Interacting with the pyembed Crate

When writing Rust code to interact with a Python interpreter, your primary area of contact will be with the pyembed crate.

The pyembed crate is a standalone crate maintained as part of the PyOxidizer project. This crate provides the core run-time functionality for PyOxidizer, such as the implementation of *PyOxidizer's custom importer*. It also exposes a high-level API for initializing a Python interpreter and running code in it.

Under the hood, the pyembed crate uses the cpython and python3-sys crates for interacting with Python's C APIs. pyembed exposes the Python object from cpython, which means that once you've initialized a Python interpreter with pyembed, you can use all the functionality in cpython to interact with that interpreter.

### 8.4.2 Initializing a Python Interpreter

Initializing an embedded Python interpreter in your Rust process is as simple as calling pyembed::MainPythonInterpreter::new(config: OxidizedPythonInterpreterConfig).

The hardest part about this is constructing the pyembed::OxidizedPythonInterpreterConfig instance.

#### Using the Default OxidizedPythonInterpreterConfig

If the pyembed crate is configured to emit build artifacts (the default), its build script will generate a Rust source file containing a fn default\_python\_config() -> pyembed::OxidizedPythonInterpreterConfig which emits a pyembed::OxidizedPythonInterpreterConfig using the configuration as defined by the utilized PyOxidizer *configuration file*. Assuming you are using the boilerplate Cargo.toml and build.rs script generated with pyoxidizer init-rust-project, the path to this generated source file will be in the PYOXIDIZER\_DEFAULT\_PYTHON\_CONFIG\_RS environment variable.

This all means that to use the auto-generated pyembed::OxidizedPythonInterpreterConfig instance with your Rust application, you simply need to do something like the following:

```
include!(env!("PYOXIDIZER_DEFAULT_PYTHON_CONFIG_RS"));
fn create_interpreter() -> Result<pyembed::MainPythonInterpreter> {
    // Calls function from include!()'d file.
    let config: pyembed::OxidizedPythonInterpreterConfig = default_python_config();
    pyembed::MainPythonInterpreter::new(config)
}
```

#### Using a Custom OxidizedPythonInterpreterConfig

If you don't want to use the default pyembed::OxidizedPythonInterpreterConfig instance, that's fine too! However, this will be slightly more complicated.

First, if you use an explicit OxidizedPythonInterpreterConfig, the *PythonInterpreterConfig* Starlark type defined in your PyOxidizer configuration file doesn't matter that much. The primary purpose of this Starlark type

is to derive the default OxidizedPythonInterpreterConfig Rust struct. And if you are using your own custom OxidizedPythonInterpreterConfig instance, you can ignore most of the arguments when creating the PythonInterpreterConfig instance.

An exception to this is the raw\_allocator argument/field. If you are using jemalloc, you will need to enable a Cargo feature when building the pyembed crate or else you will get a run-time error that jemalloc is not available.

pyembed::OxidizedPythonInterpreterConfig::default() can be used to construct a new instance, pre-populated with default values for each field. The defaults should match what the *PythonInterpreterConfig* Starlark type would yield.

The main catch to constructing the instance manually is that the custom *meta path importer* won't be able to service Python import requests unless you populate a few fields. In fact, if you just use the defaults, things will blow up pretty hard at run-time:

```
$ myapp
Fatal Python error: initfsencoding: Unable to get the locale encoding
ModuleNotFoundError: No module named 'encodings'
Current thread 0x00007fa0e2cbe9c0 (most recent call first):
Aborted (core dumped)
```

What's happening here is that Python interpreter initialization hits a fatal error because it can't import encodings (because it can't locate the Python standard library) and Python's C code is exiting the process. Rust doesn't even get the chance to handle the error, which is why we're seeing a segfault.

The reason we can't import encodings is twofold:

- 1. The default filesystem importer is disabled by default.
- 2. No Python resources are being registered with the OxidizedPythonInterpreterConfig instance.

This error can be addressed by working around either.

To enable the default filesystem importer:

```
let mut config = pyembed::OxidizedPythonInterpreterConfig::default();
config.filesystem_importer = true;
config.sys_paths.push("/path/to/python/standard/library");
```

As long as the default filesystem importer is enabled and sys.path can find the Python standard library, you should be able to start a Python interpreter.

**Hint:** The sys\_paths field will expand the special token <code>\$ORIGIN</code> to the directory of the running executable. So if the Python standard library is in e.g. the lib directory next to the executable, you can do something like <code>config.sys\_paths.push("\$ORIGIN/lib")</code>.

If you want to use the custom *PyOxidizer Importer* to import Python resources, you will need to update a handful of fields:

```
let mut config = pyembed::OxidizedPythonInterpreterConfig::default();
config.packed_resources = ...;
config.use_custom_importlib = true;
```

The packed\_resources field defines a reference to *packed resources data* (a & [u8]. This is a custom serialization format for expressing *resources* to make available to a Python interpreter. See *Python Packed Resources* for more. The easiest way to obtain this data blob is by using PyOxidizer and consuming the packed-resources build artifact/file, likely though include\_bytes!. *OxidizedFinder Python Type* can also be used to produce these data structures.

Finally, setting use\_custom\_importlib = true is necessary to enable the custom bytecode and meta path importer to be used at run-time.

### 8.4.3 Using a Python Interpreter

Once you've constructed a pyembed::MainPythonInterpreter instance, you can obtain a cpython::Python instance via .acquire\_gil() and then use it:

```
fn do_it(interpreter: &MainPythonInterpreter) -> {
    let py = interpreter.acquire_gil().unwrap();

    match pyembed::run_code(py, "print('hello, world')") {
        Ok(_) => print("python code executed successfully"),
        Err(e) => print("python error: {:?}", e),
    }
}
```

The pyembed crate exports various run\_\* functions for performing high-level evaluation of various primitives (files, modules, code strings, etc). See the pyembed crate's documentation for more.

Since CPython's API relies on static variables (sadly), if you really wanted to, you could call out to CPython C APIs directly (probably via the bindings in the python3-sys crate) and they would interact with the interpreter started by the pyembed crate. This is all unsafe, of course, so tread at your own peril.

#### 8.4.4 Finalizing the Interpreter

pyembed::MainPythonInterpreter implements Drop and it will call Py\_FinalizeEx() when called. So to terminate the Python interpreter, simply have the MainPythonInterpreter instance go out of scope or drop it explicitly.

#### 8.4.5 A Note on the pyembed APIs

The pyembed crate is highly tailored towards PyOxidizer's default use cases and the APIs are not considered extremely well polished.

While the functionality should work, the ergonomics may not be great.

It is a goal of the PyOxidizer project to support Rust programmers who want to embed Python in Rust applications. So contributions to improve the quality of the pyembed crate will likely be greatly appreciated!

### 8.5 Adding Extension Modules At Run-Time

Normally, PyOxidizer assembles all extension modules needed for a built application and the resources data embedded in the binary describes all extension modules.

The pyembed crate also supports providing additional extension modules, which are defined outside of PyOxidizer configuration files. This feature can be useful for Rust applications that want to provide extension modules through their own means and don't want to use standard Python packaging tools (like setup.py) or PyOxidizer config files for building them.

### 8.5.1 Statically Linked Extension Modules

You can inform the pyembed crate about the existence of additional Python extension modules which are statically linked into the binary.

To do this, you will need to populate the extra\_extension\_modules field of the OxidizedPythonInterpreterConfig Rust struct used to construct the Python interpreter. Simply add an entry defining the extension module's import name and a pointer to its C initialization function (often named PyInit\_<name>. e.g. if you are defining the extension module foo, the initialization function would be PyInit\_foo by convention.

Please note that Python stores extension modules in a global variable. So instantiating multiple interpreters via the pyembed interfaces may result in duplicate entries or unwanted extension modules being exposed to the Python interpreter.

### 8.5.2 Dynamically Linked Extension Modules

If you have an extension module provided as a shared library (this is typically has Python extension modules work), it will be possible to load this extension module provided that the build configuration supports loading dynamically linked Python extension modules. See *PythonExtensionModule Location Compatibility* for more on this topic.

There is not yet an explicit Rust API for loading additional dynamically linked extension modules. It is theoretically possible to add an entry to the parsed embedded resources data structure. The path of least resistance is likely to enable the standard filesystem importer and put your shared library extension module somewhere on Python's sys.path.

# 8.6 Porting a Python Application to Rust

PyOxidizer can be used to gradually port a Python application to Rust. What we mean by this is that Python code in an application would slowly be rewritten in Rust.

#### 8.6.1 Overview

When porting a Python application to Rust, the goal is to port Python code - and possibly Python C extension code - to Rust. Parts of the Rust code will presumably need to call into Python code and vice-versa.

When porting code to Rust, there are essentially two *flavors* of Rust code that will be written and executed:

- 1. Vanilla Rust code
- 2. Python-flavored Rust code

Vanilla Rust code is standard Rust code. It is what you would write if authoring a Rust-only project.

*Python-flavored* Rust code is Rust code that interacts with the Python C API. It is regular Rust code, of course, but it is littered with references to *PyObject* and function calls into the Python C API (although these function calls may be abstracted so you don't have to use unsafe).

These different *flavors* of Rust code dictate different approaches to porting. Both *flavors*/approaches can be used simultaneously when porting an application to Rust.

Vanilla Rust code will supplement the boilerplate Rust code that PyOxidizer uses to define and build a standalone executable embedded Python. See *Extending Rust Projects* for more.

*Python-flavored* Rust code typically involves writing Python extension modules in Rust. In this approach, you create a Python extension modules implemented in Rust and then make them available to the Python interpreter, which is managed by a Rust project.

### 8.6.2 Extending Rust Projects

When building an application from a standalone pyoxidizer.bzl file, PyOxidizer creates and builds a temporary, boilerplate Rust project behind the scenes. This Rust project has just enough code to initialize and run an embedded Python interpreter. That's the extent of the Rust code.

PyOxidizer also supports persistent Rust projects. In this mode, you have full control over the Rust project and can add custom Rust code to it as you desire. In this mode, you can run Rust code independent of the Python interpreter.

Supplementing the Rust code contained in your executable gives you the power to run arbitrary Rust code however you see fit. Here are some common scenarios this can enable:

- Implementing argument parsing in Rust instead of Python. This could allow you to parse out the sub-command being invoked and dispatch to pure Rust code paths if possible, falling back to running Python code only if necessary.
- Running a *forking* server, which doesn't start a Python interpreter until an event occurs.
- Starting a thread with a high-performance application component implemented in Rust. For example, you could run a thread servicing a high-performance logging subsystem or HTTP server implemented in Rust and have that thread interact with a Python interpreter via a pipe or some other handle.

#### **Getting Started**

To extend a Rust project with custom Rust code, you'll first want to materialize the boilerplate Rust project used by PyOxidizer:

\$ pyoxidizer init-rust-project myapp

See Rust Projects for details on the files materialized by this command.

If you are using version control, now would be a good time to add the created files to version control. e.g.:

```
$ git add myapp
$ git commit -m 'create boilerplate PyOxidizer project'
```

From here, your next steps are to modify the Rust project to do something new and different.

The auto-generated src/main.rs file contains the main() function used as the entrypoint for the Rust executable. The default file will simply instantiate a Python interpreter from a configuration, run that interpreter, then exit the process.

To extend your application with custom Rust code, simply add custom code to main (). e.g.

```
fn main() {
    println!("hello from Rust!")
    // Code auto-generated by ``pyoxidizer init-rust-project`` goes here.
    // ...
}
```

That is literally all there is to it!

To build your custom Rust project, pyoxidizer build is the most robust way to do that. But it is also possible to use cargo build.

#### What Can Go Wrong

#### pyoxidizer Not Found or Rust Code Version Mismatch

When using cargo build, the pyoxidizer executable will be invoked behind the scenes. This requires that executable to be on PATH and for the version to be compatible with the Rust code you are trying to build. (The Rust APIs do change from time to time.)

If the pyoxidizer executable is not on PATH or its version doesn't match the Rust code, you can forcefully tell the Rust build system which pyoxidizer executable to use:

\$ PYOXIDIZER\_EXE=/path/to/pyoxidizer cargo build

# thread 'main' panicked at 'jemalloc is not available in this build configuration'

If you see this error, the problem is that the Python interpreter configuration says to use *jemalloc* as the memory allocator but the Rust project was built without *jemalloc* support. This is likely because the default Rust project features in Cargo.toml don't include *jemalloc* by default.

You can resolve this issue by either disabling jemalloc in the Python configuration or by enabling jemalloc in Rust.

To disable jemalloc, open your pyoxidizer.bzl file and find the definition of raw\_allocator. You can set it to raw\_allocator="system" so Python uses the system memory allocator instead of jemalloc.

To enable jemalloc, you have a few options.

First, you could build the Rust project with jemalloc support:

\$ cargo build --features jemalloc

Or, you modify Cargo.toml so the *jemalloc* feature is enabled by default:

.. code-block:: toml

[features] default = ["build-mode-pyoxidizer-exe", "jemalloc"]

*jemalloc* is typically a faster allocator than the system allocator. So if you care about performance, you may want to use it.

#### 8.6.3 Implementing Python Extension Modules in Rust

If you want to port a Python application to Rust, chances are that you will need to have Rust and Python code interact with each other. A common way to do this is to implement Python extensions in Rust so that Rust code will be invoked as a Python interpreter is running.

There are two ways Rust-implemented Python extension modules can be consumed by PyOxidizer:

- 1. Define them via Python packaging tools (e.g. via a setup.py file for your Python package).
- 2. Define them in Rust code and register them as a built-in extension module.

#### Python Built Rust Extension Modules

If you've defined a Rust Python extension module via a Python package build tool (e.g. inside a setup.py), PyOxidizer should automatically detect said extension module as part of packaging the corresponding Python package: there is no need to take special action to tell PyOxidizer it is a Rust extension, as this is all handled by Python packaging tools invoked as part of processing your pyoxidizer.bzl file.

See Packaging User Guide for more.

The topic of authoring Python extension modules implemented in Rust is arguably outside the scope of this documentation. A search engine search for Rust Python extension should set you on the right track.

#### **Built-in Rust Extension Modules**

A Python extension module is defined as a PyInit\_\_<name> function which is called to initialize an extension module. Typically, Python extension modules are compiled as standalone shared libraries, which are then loaded into a process, after which their PyInit\_\_<name> function is called.

But Python has an additional mechanism for defining extension modules: *built-ins*. A *built-in* extension module is simply an extension module whose PyInit\_\_<name> function is already present in the process address space. Typically, these are extensions that are part of the Python distribution itself and are compiled directly into libpython.

When you instantiate a Python interpreter, you give it a list of the available *built-in* Python extension modules. And PyOxidizer's pyembed crate allows you to supplement the default list with custom extensions.

To use *built-in* extension modules implemented in Rust, you'll need to implement said extension module in Rust, either as part of your application's Rust crate or as part of a different crate. Either way, you'll need to extend the boilerplate Rust project code (see *Extending Rust Projects*) and tell it about additional *built-in* extension modules. See *Adding Extension Modules At Run-Time* for instructions on how to do this.

The tricky part here is implementing your Rust extension module.

You probably want to use the cpython or PyO3 Rust crates for interfacing with the CPython API, as these provide an interface that is more ergonomic and doesn't require use of unsafe  $\{ \}$ . Use of these crates is beyond the scope of the PyOxidizer documentation.

If you attempt to use the cpython or PyO3 macros for defining a Python extension module, you'll likely run into problems because these assume that extension modules are standalone shared libraries, which isn't the case for *built-in* extension modules!

If you attempt to use a separate Rust crate to define your extension module, you may run into Python symbol issues at link time because the build system for the cpython and PyO3 crates will use their own logic for locating a Python interpreter and that interpreter may not have a configuration that is compatible with the one embedded in your PyOxidizer binary!

At the end of the day, all you need to register a *built-in* extension module with PyOxidizer is an extern "C" fn () -> \*mut python3\_sys::PyObject. Here is the boilerplate for defining a Python extension module in Rust (this uses the cpython crate).

```
use python3_sys as pyffi;
use cpython::{PyErr, PyModule, PyObject};
static mut MODULE_DEF: pyffi::PyModuleDef = pyffi::PyModuleDef {
    m_base: pyffi::PyModuleDef_HEAD_INIT,
    m_name: std::ptr::null(),
    m_doc: std::ptr::null(),
    m_size: std::mem::size_of::<ModuleState>() as isize,
    m_methods: 0 as *mut _,
    m_slots: 0 as *mut _,
    m_traverse: None,
    m_free: None,
    m_free: None,
};
```

```
#[allow(non_snake_case)]
pub extern "C" fn PyInit_my_module() -> *mut pyffi::PyObject {
    let py = unsafe { cpython::Python::assume_gil_acquired() };
    unsafe {
        if MODULE_DEF.m_name.is_null() {
            MODULE_DEF.m_name = "my_module".as_ptr() as *const _;
            MODULE_DEF.m_doc = "usage docs".as_ptr() as *const _;
        }
    }
    let module = unsafe { pyffi::PyModule_Create(&mut MODULE_DEF) };
    if module.is_null() {
        return module;
    1
    let module = match unsafe { pyffi::from_owned_ptr(py, module).cast_into::
\leftrightarrow < PyModule > (py) } {
        Ok(m) => m_{\prime}
        Err(e) => {
            PyErr::from(e).restore(py);
            return std::ptr::null_mut();
        }
    };
    match module_init(py, &module) {
        Ok(()) => module.into_object().steal_ptr(),
        Err(e) => {
            e.restore(py);
            std::ptr::null_mut()
        }
    }
```

If you want a concrete example of what this looks like and how to do things like define Python types and have Python functions implemented in Rust, do a search for PyInit\_oxidized\_importer in the source code of the pyembed crate (which is part of the PyOxidizer repository) and go from there.

The documentation for authoring Python extension modules and using the Python C API is well beyond the scope of this document. A good place to start is the official documentation.

# CHAPTER 9

### Frequently Asked Questions

### 9.1 Where Can I Report Bugs / Send Feedback / Request Features?

At https://github.com/indygreg/PyOxidizer/issues

## 9.2 Why Build Another Python Application Packaging Tool?

It is true that several other tools exist to turn Python code into distributable applications! *Comparisons to Other Tools* attempts to exhaustively compare PyOxidizer to these myriad of tools. (If a tool is missing or the comparison incomplete or unfair, please file an issue so Python application maintainers can make better, informed decisions!)

The long version of how PyOxidizer came to be can be found in the Distributing Standalone Python Applications blog post. If you really want to understand the motivations for starting a new project rather than using or improving an existing one, read that post.

If you just want the extra concise version, at the time PyOxidizer was conceived, there were no Python application packaging/distribution tool which satisfied **all** of the following requirements:

- Works across all platforms (many tools target e.g. Windows or macOS only).
- Does not require an already-installed Python on the executing system (rules out e.g. zip file based distribution mechanisms).
- Has no special system requirements (e.g. SquashFS, container runtimes).
- Offers startup performance no worse than traditional python execution.
- · Supports single file executables with none or minimal system dependencies.

# 9.3 Can Python 2.7 Be Supported?

In theory, yes. However, it is considerable more effort than Python 3. And since Python 2.7 is being deprecated in 2020, in the project author's opinion it isn't worth the effort.

# 9.4 Why is Python 3.8 Required?

Python 3.8 contains a new C API for controlling how embedded Python interpreters are started. This makes the run-time code that native binaries execute much, much simpler.

PyOxidizer versions up to 0.7 supported Python 3.7. But a decision was made to require Python 3.8 because the runtime code to manage the Python interpreter was vastly simpler and less prone to bugs. Given that Python 3.8 is mostly backwards compatible with Python 3.7, this wasn't perceived as a significant annoyance.

## 9.5 No python interpreter found of version 3.\* Error When Building

This is due to a dependent crate insisting that a Python executable exist on PATH. Set the PYTHON\_SYS\_EXECUTABLE environment variable to the path of a Python 3.7 executable and try again. e.g.:

```
# UNIX
$ export PYTHON_SYS_EXECUTABLE=/usr/bin/python3.7
# Windows
$ SET PYTHON_SYS_EXECUTABLE=c:\python37\python.exe
```

**Note:** The pyoxidizer tool should take care of setting PYTHON\_SYS\_EXECUTABLE and prevent this error. If you see this error and you are building with pyoxidizer, it is a bug that should be reported.

## 9.6 Why Rust?

This is really 2 separate questions:

- Why choose Rust for the run-time/embedding components?
- Why choose Rust for the build-time components?

PyOxidizer binaries require a *driver* application to interface with the Python C API and that *driver* application needs to compile to native code in order to provide a *native* executable without requiring a run-time on the machine it executes on. In the author's opinion, the only appropriate languages for this were C, Rust, and maybe C++.

Of those 3, the project's author prefers to write new projects in Rust because it is a superior systems programming language that has built on lessons learned from decades working with its predecessors. The author prefers technologies that can detect and eliminate entire classes of bugs (like buffer overflow and use-after-free) at compile time. On a less-opinionated front, Rust's built-in build system support means that we don't have to spend considerable effort solving hard problems like cross-compiling. Implementing the embedding component in Rust also creates interesting opportunities to embed Python in Rust programs. This is largely an unexplored area in the Python ecosystem and the author hopes that PyOxidizer plays a part in more people embedding Python in Rust.

For the non-runtime packaging side of PyOxidizer, pretty much any programming language would be appropriate. The project's author initially did prototyping in Python 3 but switched to Rust for synergy with the the run-time driver and because Rust had working solutions for several systems-level problems, such as parsing ELF, DWARF, etc executables, cross-compiling, integrating custom memory allocators, etc. A minor factor was the author's desire to learn more about Rust by starting a *real* Rust project.

## 9.7 Why is the Rust Code... Not Great?

This is the project author's first real Rust project. Suggestions to improve the Rust code would be very much appreciated!

Keep in mind that the pyoxidizer crate is a build-time only crate and arguably doesn't need to live up to quality standards as crates containing run-time code. Things like aggressive .unwrap() usage are arguably tolerable.

The run-time code that produced binaries run (pyembed) is held to a higher standard and is largely panic! free.

### 9.8 What is the *Magic Sauce* That Makes PyOxidizer Special?

There are 2 technical achievements that make PyOxidizer special.

First, PyOxidizer consumes Python distributions that were specially built with the aim of being used for standalone/distributable applications. These custom-built Python distributions are compiled in such a way that the resulting binaries have very few external dependencies and run on nearly every target system. Other tools that produce standalone Python binaries often rely on an existing Python distribution, which often doesn't have these characteristics.

Second is the ability to import .py/.pyc files from memory. Most other self-contained Python applications rely on Python's zipimporter or do work at run-time to extract the standard library to a filesystem (typically a temporary directory or a FUSE filesystem like SquashFS). What PyOxidizer does is expose the .py/.pyc modules data to the Python interpreter via a Python extension module built-in to the binary.

During Python interpreter initialization, a custom Rust-implemented Python importer is registered and takes over all imports. Requests for modules are serviced from the parsed data structure defining known modules.

Follow the Documentation link for the pyembed crate for an overview of how the in-memory import machinery works.

## 9.9 Can Applications Import Python Modules from the Filesystem?

#### Yes!

While PyOxidizer supports importing Python resources from in-memory, it also supports filesystem-based import like traditional Python applications.

This can be achieved by adding Python resources to a non *in-memory* resource location (see *Manag-ing How Resources are Added*) or by enabling Python's standard filesystem-based importer by enabling filesystem\_importer=True (see *PythonInterpreterConfig*).

# 9.10 error while loading shared libraries: libcrypt. so.1: cannot open shared object file: No such file or directory When Building

If you see this error when building, it is because your Linux system does not conform to the Linux Standard Base Specification, does not provide a libcrypt.so.1 file, and the Python distribution that PyOxidizer attempts to run to compile Python source modules to bytecode can't execute.

Fedora 30+ are known to have this issue. A workaround is to install the libxcrypt-compat on the machine running pyoxidizer. See https://github.com/indygreg/PyOxidizer/issues/89 for more info.

# CHAPTER 10

### **Project Status**

PyOxidizer is functional and works for many use cases. However, there are still a number of rough edges, missing features, and known limitations. Please file issues at https://github.com/indygreg/PyOxidizer/issues!

### 10.1 What's Working

The basic functionality of creating binaries that embed a self-contained Python works on Linux, Windows, and macOS. The general approach should work for other operating systems.

Starlark configuration files allow extensive customization of packaging and run time behavior. Many projects can be successfully packaged with PyOxidizer today.

### **10.2 Major Missing Features**

#### 10.2.1 An Official Build Environment

Compiling binaries that work on nearly every target system is hard. On Linux, things like glibc symbol versions from the build machine can leak into the built binary, effectively requiring a new Linux distribution to run a binary.

In order to make the binary build process robust, we will need to provide an execution environment in which to build portable binaries. On Linux, this likely entails making something like a Docker image available. On Windows and macOS, we might have to provide a tarball. In all cases, we want this environment to be integrated into pyoxidizer build so end users don't have to worry about jumping through hoops to build portable binaries.

#### **10.2.2 Native Extension Modules**

Using compiled extension modules (e.g. C extensions) is partially supported.

Building C extensions to be embedded in the produced binary works for Windows, Linux, and macOS.

Support for extension modules that link additional macOS frameworks not used by Python itself is not yet implemented (but should be easy to do).

Support for cross-compiling extension modules (including to MUSL) does not work. (It may appear to work and break at linking or run-time.)

We also do not yet provide a build environment for C extensions. So unexpected behavior could occur if e.g. a different compiler toolchain is used to build the C extensions from the one that produced the Python distribution.

See also C and Other Native Extension Modules.

### 10.2.3 Incomplete pyoxidizer Commands

pyoxidizer add and pyoxidizer analyze aren't fully implemented.

There is no pyoxidizer upgrade command.

Work on all of these is planned.

### 10.2.4 More Robust Packaging Support

Currently, we produce an executable via Cargo. Often a self-contained executable is not suitable. We may have to run some Python modules from the filesystem because of limitations in those modules. In addition, some may wish to install custom files alongside the executable.

We want to add a myriad of features around packaging functionality to facilitate these things. This includes:

- Support for \_\_\_\_\_file\_\_\_.
- A build mode that produces an instrumented binary, runs it a few times to dump loaded modules into files, then builds it again with a pruned set of resources.

### **10.2.5 Making Distribution Easy**

We don't yet have a good story for the *distributing* part of the application distribution problem. We're good at producing executables. But we'd like to go the extra mile and make it easier for people to produce installers, .dmg files, tarballs, etc.

This includes providing build environments for e.g. non-MUSL based Linux executables.

It also includes support for auditing for license compatibility (e.g. screening for GPL components in proprietary applications) and assembling required license texts to satisfy notification requirements in those licenses.

### 10.2.6 Partial Terminfo and Readline Support

PyOxidizer has partial support for detecting terminfo databases. See *Terminfo Database* for more.

There's a good chance PyOxidizer's ability to locate terminfo databases in the long tail of Python distributions is lacking. And PyOxidizer doesn't currently make it easy to distribute a terminfo database alongside the application.

At this time, proper terminal interaction in PyOxidizer applications may be hit-or-miss.

Please file issues at https://github.com/indygreg/PyOxidizer/issues reporting known problems with terminal interaction or to request new features for terminal interaction, terminfo database support, etc.

### 10.2.7 Standalone Resource Files

Currently, indexed resources are always embedded in built binaries. This means that if you are producing multiple binaries, there will be redundant copies of resources in each binary.

Eventually, PyOxidizer will support emitting standalone resources files and enabling binaries to reference those files. This will enable multiple binaries to share the same resource collection.

This functionality exists in the run-time Rust code today. But it isn't turnkey and isn't exposed to Starlark.

### **10.3 Lesser Missing Features**

### **10.3.1 Python Version Support**

Python 3.8 and 3.9 are currently supported. Older versions of PyOxidizer (through version 0.7) supported Python 3.7. See *Why is Python 3.8 Required?* for why we require these Python versions.

#### **10.3.2 Reordering Resource Files**

There is not yet support for reordering .py and .pyc files in the binary. This feature would facilitate linear read access, which could lead to faster execution.

#### **10.3.3 Compressed Resource Files**

Binary resources are currently stored as raw data. They could be stored compressed to keep binary size in check (at the cost of run-time memory usage and CPU overhead).

#### **10.3.4 Nightly Rust Required on Windows**

Windows currently requires a Nightly Rust to build (you can set the environment variable RUSTC\_BOOTSTRAP=1 to work around this) because the static-nobundle library type is required. https://github.com/rust-lang/rust/issues/ 37403 tracks making this feature stable. It *might* be possible to work around this by adding an \_\_imp\_ prefixed symbol in the right place or by producing a empty import library to satisfy requirements of the static linkage kind. See https://github.com/rust-lang/rust/issues/26591#issuecomment-123513631 for more.

### 10.3.5 Cross Compiling

Cross compiling is not yet supported. We hope to and believe we can support this someday. We would like to eventually get to a state where you can e.g. produce Windows and macOS executables from Linux. It's possible.

### **10.3.6 Configuration Files**

Naming and semantics in the configuration files can be significantly improved. There's also various missing packaging functionality.

# **10.4 Eventual Features**

The immediate goal of PyOxidizer is to solve packaging and distribution problems for Python applications. But we want PyOxidizer to be more than just a packaging tool: we want to add additional features to PyOxidizer to bring extra value to the tool and to demonstrate and/or experiment with alternate ways of solving various problems that Python applications frequently encounter.

### 10.4.1 Lazy Module Loading

When a Python module is imported, its code is evaluated. When applications consist of dozens or even hundreds of modules, the overhead of executing all this code at import time can be substantial and add up to dozens of milliseconds of overhead - all before your application runs a meaningful line of code.

We would like PyOxidizer to provide lazy module importing so Python's import machinery can defer evaluating a module's code until it is actually needed. With features in modern versions of Python 3, this feature could likely be enabled by default. And since many PyOxidizer applications are *frozen* and have total knowledge of all importable modules at build time, PyOxidizer could return a *lazy* module object after performing a simple Rust HashMap lookup. This would be extremely fast.

### **10.4.2 Alternate Module Serialization Techniques**

Related to lazy module loading, there is also the potential to explore alternate module serialization techniques. Currently, the way PyOxidizer and .pyc files work is that a Python code object is serialized with the marshal module. At module load time, the code object is deserialized and then executed. This deserialization plus code execution has overhead.

It is possible to devise alternate serialization and load techniques that don't rely on marshal and possibly bypass having to run as much code at module load time. For example, one could devise a format for serializing various PyObject types and then adjusting pointers inside the structs at run time. This is kind of a crazy idea. But it could work.

### 10.4.3 Module Order Tracing

Currently, resource data is serialized on disk in alphabetical order according to the resource name. e.g. the bar module is serialized before the foo module.

We would like to explore a mechanism to record the order in which modules are loaded as part of application execution and then reorder the serialized modules such that they are stored in load order. This will facilitate linear reads at application run time and possibly provide some performance wins (especially on devices with slow I/O).

### 10.4.4 Module Import Performance Tracing

PyOxidizer has near total visibility into what Python's module importer is doing. It could be very useful to provide forensic output of what modules import what, how long it takes to import various modules, etc.

CPython does have some support for module importing tracing. We think we can go a few steps farther. And we can implement it more easily in Rust than what CPython can do in C. For example, with Rust, one can use the inferno crate to emit flame graphs directly from Rust, without having to use external tools.

### 10.4.5 Built-in Profiler

There's potential to integrate a built-in profiler into PyOxidizer applications. The excellent py-spy sampling profiler (or the core components of it) could potentially be integrated directly into PyOxidizer such that produced applications could self-profile with minimal overhead.

It should also be possible for PyOxidizer to expose mechanisms for Rust to receive callbacks when Python's profiling and tracing hooks fire. This could allow building a powerful debugger or tracer in Rust.

### 10.4.6 Command Server

A known problem with Python is its startup overhead. The maintainer of PyOxidizer has raised this issue on Python's mailing list a few times.

PyOxidizer helps with this problem by eliminating explicit filesystem I/O and allowing modules to be imported faster. But there's only so much that can be done and startup overhead can still be a problem.

One strategy to combat this problem is the use of persistent *command server daemons*. Essentially, on the first invocation of a program you spawn a background process running Python. That process listens for *command requests* on a pipe, socket, etc. You send the current command's arguments, environment variables, other state, etc to the background process. It uses its Python interpreter to execute the command and send results back to the main process. On the 2nd invocation of your program, the Python process/interpreter is already running and meaningful Python code can be executed immediately, without waiting for the Python interpreter and your application code to initialize.

This approach is used by the Mercurial version control tool, for example, where it can shave dozens of milliseconds off of hg command service times.

PyOxidizer could potentially support *command servers* as a built-in feature for *any* Python application.

### 10.4.7 PyO3

PyO3 are alternate Rust bindings to Python from rust-cpython, which is what pyembed currently uses.

The PyO3 bindings seem to be ergonomically better than *rust-cpython*. PyOxidizer may switch to PyO3 someday.

# CHAPTER 11

### Comparisons to Other Tools

What makes PyOxidizer different from other Python packaging and distribution tools? Read on to find out!

If you are curious why PyOxidizer's creator felt the need to create a new tool, see *Why Build Another Python Applica*tion Packaging Tool? in the FAQ.

**Important:** It is important for Python application maintainers to make informed decisions about their use of packaging tools. If you feel the comparisons in this document are incomplete or unfair, please file an issue so this page can be improved.

### 11.1 PyInstaller

PyInstaller is a tool to convert regular python scripts to "standalone" executables. The standard packaging produces a tiny executable and a custom directory structure to host dynamic libraries and Python code (zipped compiled byte-code). PyInstaller can produce a self-contained executable file containing your application, however, at run-time, PyInstaller will extract binary files and a custom ZlibArchive to a temporary directory then import modules from the filesystem. PyOxidizer typically skips this step and loads modules directly from memory using zero-copy. This makes PyOxidizer executables significantly faster to start.

Currently a big difference is that PyOxidizer needs to build all the binary dependencies from scratch to facilitate linking into single file, PyInstaller can work with normal Python packages with a complex system of hooks to find the runtime dependencies, this allow a lot of not easy to build packages like PyQt to work out of the box.

### 11.2 py2exe

py2exe is a tool for converting Python scripts into Windows programs, able to run without requiring an installation.

The goals of py2exe and PyOxidizer are conceptually very similar.

One major difference between the two is that py2exe works on just Windows whereas PyOxidizer works on multiple platforms.

One trick that py2exe employs is that it can load libpython and Python extension modules (which are actually dynamic link libraries) and other libraries from memory - not filesystem files. They employ a really clever hack to do this! This is similar in nature to what Google does internally with a custom build of glibc providing a dlopen\_from\_offset(). Essentially, py2exe embeds DLLs and other entities as *resources* in the PE file (the binary executable format for Windows) and is capable of loading them from memory. This allows py2exe to run things from a single binary, just like PyOxidizer! The main difference is py2exe relies on clever DLL loading tricks rather than PyOxidizer's approach of using custom builds of Python (which exist as a single binary/library) to facilitate this. This is a really clever solution and py2exe's authors deserve commendation for pulling this off!

The approach to packaging that py2exe and PyOxidizer take is substantially different. py2exe embeds itself into setup.py as a distutils extension. PyOxidizer wants to exist at a higher level and interact with the output of setup.py rather than get involved in the convoluted mess of distutils internals. This enables PyOxidizer to provide value beyond what setup.py/distutils can provide.

py2exe is a mature Python packaging/distribution tool for Windows. It offers a lot of similar functionality to PyOxidizer.

# 11.3 py2app

py2app is a setuptools command which will allow you to make standalone application bundles and plugins from Python scripts.

py2app only works on macOS. This makes it like a macOS version of py2exe. Most *comparisons to py2exe* are analogous for py2app.

# 11.4 cx\_Freeze

cx\_Freeze is a set of scripts and modules for freezing Python scripts into executables.

The goals of cx\_Freeze and PyOxidizer are conceptually very similar.

Like other tools in the *produce executables* space, cx\_Freeze packages Python traditionally. On Windows, this entails shipping a pythonXY.dll. cx\_Freeze will also package dependent libraries found by binaries you are shipping. This introduces portability problems, especially on Linux.

PyOxidizer uses custom Python distributions that are built in such a way that they are highly portable across machines. PyOxidizer can also produce single file executables.

## 11.5 Shiv

Shiv is a packager for zip file based Python applications. The Python interpreter has built-in support for running self-contained Python applications that are distributed as zip files.

Shiv requires the target system to have a Python executable and for the target to support shebangs in executable files. This is acceptable for controlled \*NIX environments. It isn't acceptable for Windows (which doesn't support shebangs) nor for environments where you can't guarantee an appropriate Python executable is available.

Also, by distributing our own Python interpreter with the application, PyOxidizer has stronger guarantees about the run-time environment. For example, your application can aggressively target the latest Python version. Another benefit of distributing your own Python interpreter is you can run a Python interpreter with various optimizations,

such as profile-guided optimization (PGO) and link-time optimization (LTO). You can also easily configure custom memory allocators or tweak memory allocators for optimal performance.

# 11.6 PEX

PEX is a packager for zip file based Python applications. For purposes of comparison, PEX and Shiv have the same properties. See *Shiv* for this comparison.

# 11.7 XAR

XAR requires the use of SquashFS. SquashFS requires Linux.

PyOxidizer is a target native executable and doesn't require any special filesystems or other properties to run.

# 11.8 Docker / Running a Container

It is increasingly popular to distribute applications as self-contained container environments. e.g. Docker images. This distribution mechanism is effective for Linux users.

PyOxidizer will almost certainly produce a smaller distribution than container-based applications. This is because many container-based applications contain a lot of extra content that isn't needed by the processes within.

PyOxidizer also doesn't require a container execution environment. Not every user has the capability to run certain container formats. However, nearly every user can run an executable.

At run time, PyOxidizer executes a native binary and doesn't have to go through any additional execution layers. Contrast this with Docker, which uses HTTP requests to create containers, set up temporary filesystems and networks for the container, etc. Spawning a process in a new Docker container can take hundreds of milliseconds or more. This overhead can be prohibitive for low latency applications like CLI tools. This overhead does not exist for PyOxidizer executables.

# 11.9 Nuitka

Nuitka can compile Python programs to single executables. And the emphasis is on *compile*: Nuitka actually converts Python to C and compiles that. Nuitka is effectively an alternate Python interpreter.

Nuitka is a cool project and purports to produce significant speed-ups compared to CPython!

Since Nuitka is effectively a new Python interpreter, there are risks to running Python in this environment. Some code has dependencies on CPython behaviors. There may be subtle bugs are lacking features from Nuitka. However, Nuitka supposedly supports every Python construct, so many applications should *just work*.

Given the performance benefits of Nuitka, it is a compelling alternative to PyOxidizer.

# 11.10 PyRun

PyRun can produce single file executables. The author isn't sure how it works. PyRun doesn't appear to support modern Python versions. And it appears to require shared libraries (like bzip2) on the target system. PyOxidizer supports the latest Python and doesn't require shared libraries that aren't in nearly every environment.

# 11.11 pynsist

pynsist is a tool for building Windows installers for Python applications. pynsist is very similar in spirit to PyOxidizer.

A major difference between the projects is that pynsist focuses on solving the application distribution problem on Windows where PyOxidizer aims to solve larger problems around Python application distribution, such as performance optimization (via loading Python modules from memory instead of the filesystem).

PyOxidizer has yet to invest significantly into making producing distributable artifacts (such as Windows installers) simple, so pynsist still has an advantage over PyOxidizer here.

# 11.12 Bazel

Bazel has Python rules for building Python binaries and libraries. From a high level, it works similarly to how PyOxidizer's Starlark config files allow you to perform much of the same actions.

The executables produced by py\_binary are significantly different from what PyOxidizer does, however.

An executable produced by py\_binary is a glorified self-executing zip file. At run time, it extracts Python resources to a temporary directory and then runs a Python interpreter against them. The approach is similar in nature to what Shiv and PEX do.

PyOxidizer, by contrast, produces a specialized binary containing the Python interpreter and allows you to embed Python resources inside that binary, enabling Python modules to be imported without the overhead of writing a temporary directory and extracting a zip file.

# CHAPTER 12

# Contributing to PyOxidizer

This page documents how to contribute to PyOxidizer.

# 12.1 As a User

PyOxidizer is currently a relative young project and could substantially benefit from reports from its users. Try to package applications with PyOxidizer. If things break or are hard to learn, file an issue on GitHub. You can also join the pyoxidizer-users mailing list to report your experience, get in touch with other users, etc.

# 12.2 As a Developer

If you would like to contribute to the code behind PyOxidizer, you can do so using a standard GitHub workflow through the canonical project home at https://github.com/indygreg/PyOxidizer.

Please note that PyOxidizer's maintainer can be quite busy from time to time. So please be patient. He will be patient with you.

The documentation around how to hack on the PyOxidizer codebase is a bit lacking. Sorry for that!

The most important command for contributors to know how to run is cargo run --bin pyoxidizer. This will compile the pyoxidizer executable program and run it. Use it like cargo run --bin pyoxidizer -- init ~/tmp/myapp to run pyoxidizer init ~/tmp/myapp for example. If you just run cargo build, it will also build the pyapp project, which is an in-repo project that attempts to use PyOxidizer.

# **12.3 Financial Contributions**

If you would like to thank the PyOxidizer maintainer via a financial contribution, you can do so on his Patreon or via PayPal.

Financial contributions of any amount are appreciated. Please do not feel obligated to donate money: only donate if you are financially able and feel the maintainer deserves the reward for a job well done.

# CHAPTER 13

# **Project History**

Work on PyOxidizer started in November 2018 by Gregory Szorc.

# 13.1 Blog Posts

- Announcing the 0.9 Release of PyOxidizer (2020-10-18)
- Announcing the 0.8 Release of PyOxidizer (2020-10-12)

- Distributing Standalone Python Applications (2018-12-18)

# **13.2 Version History**

## 13.2.1 0.9.0

Released October 18, 2020.

#### **Backwards Compatibility Notes**

• The pyembed::OxidizedPythonInterpreterConfig Rust struct now contains an argv field that can be used to control the population of sys.argv.

- The pyembed::OxidizedPythonInterpreterConfig Rust struct now contains a set\_missing\_path\_configuration field that can be used to control the automatic run-time population of missing *path configuration* fields.
- The configure\_locale interpreter configuration setting is enabled by default. (#294)
- The pyembed::OxidizedPythonInterpreterConfig Rust struct now contains an exe field holding the path of the currently running executable.
- At run-time, the program\_name and home fields of the embedded Python interpreter's path configuration are now always set to the currently running executable and its directory, respectively, unless explicit values have been provided.
- The packed resource data version has changed from 2 to 3 in order to support storing arbitrary file data. Support for reading and writing version 2 has been removed. Packed resources blobs will need to be regenerated in order to be compatible with new versions of PyOxidizer.
- The pyembed::OxidizedPythonInterpreterConfig Rust struct had its packed\_resources field changed from Option<&'a [u8]> to Vec<&'a [u8]> so multiple resource inputs can be specified.
- The PythonDistribution Starlark type no longer has extension\_modules(), package\_resources() and source\_modules() methods. Use PythonDistribution. python\_resources() instead.

#### **New Features**

- A print (\*args) function is now exposed to Starlark. This function is documented as a Starlark built-in but isn't provided by the Rust Starlark implementation by default. So we've implemented it ourselves. (#292)
- The new pyoxidizer find-resources command can be used to invoke PyOxidizer's code for scanning files for resources. This command can be used to debug and triage bugs related to PyOxidizer's custom code for finding and handling resources.
- Executables built on Windows now embed an application manifest that enables long paths support. (#197)
- The Starlark PythonPackagingPolicy type now exposes an allow\_files attribute controlling whether files can be added as resources.
- The Starlark PythonPackagingPolicy type now exposes file\_scanner\_classify\_files and file\_scanner\_emit\_files attributes controlling whether file scanning attempts to classify files and whether generic file instances are emitted, respectively.
- The Starlark PythonPackagingPolicy type now exposes include\_classified\_resources and include\_file\_resources attributes to control whether certain classes of resources have their add\_include attribute set by default.
- The Starlark PythonPackagingPolicy type now has a set\_resources\_handling\_mode() method to quickly apply a mode for resource handling.
- The Starlark PythonDistribution type now has a python\_resources() method for obtaining all Python resources associated with the distribution.
- Starlark File instances can now be added to resource collections via PythonExecutable. add\_python\_resource() and PythonExecutable.add\_python\_resources().

#### **Bug Fixes**

• Fix some documentation references to outdated Starlark configuration syntax (#291).

- Emit only the PythonExtensionModule built with our patched distutils instead of emitting 2 PythonExtensionModule for the same named module. This should result in compiled Python extension modules being usable as built-in extensions instead of being recognized as only shared libraries.
- Fix typo preventing the Starlark method PythonExecutable.read\_virtualenv() from being defined. (#297)
- The default value of the Starlark PythonInterpreterConfig.configure\_locale field is True instead of None (effectively False since the default .profile value is isolated). This results in Python's encodings being more reasonable by default, which helps ensure non-ASCII arguments are interpreted properly. (#294)
- Properly serialize module\_search\_paths to Rust code. Before, attempting to set PythonInterpreterConfig.module\_search\_paths in Starlark would result in malformed Rust code being generated. (#298)

#### **Other Relevant Changes**

- The pyembed Rust crate now calls PyConfig\_SetBytesArgv or PyConfig\_SetArgv() to initialize argv instead of PySys\_SetObject(). The encoding of string values should also behave more similarly to what python does.
- The pyembed tests exercising Python interpreters now run in separate processes. Before, Rust would instantiate multiple interpreters in the same process. However, CPython uses global variables and APIs (like setlocale()) that also make use of globals and process reuse resulted in tests not having pristine execution environments. All tests now run in isolated processes and should be much more resilient.
- When PyOxidizer invokes a subprocess and logs its output, stderr is now redirected to stdout and logged as a unified stream. Previously, stdout was logged and stderr went to the parent process stderr.
- There now exists documentation on how to create an executable that behaves like python.
- The documentation on binary portability has been overhauled to go in much greater detail.
- The list of standard library test packages is now obtained from the Python distribution metadata instead of a hardcoded list in PyOxidizer's source code.

## 13.2.2 0.8.0

Released October 12, 2020.

#### **Backwards Compatibility Notes**

- The default Python distributions have been upgraded to CPython 3.8.6 (from 3.7.7) and support for Python 3.7 has been removed.
- On Windows, the default\_python\_distribution() Starlark function now defaults to returning a standalone\_dynamic distribution variant, meaning that it picks a distribution that can load standalone .pyd Python extension modules by default.
- The *standalone* Python distributions are now validated to be at least version 5 of the distribution format. If you are using the default Python distributions, this change should not affect you.
- Support for packaging the official Windows embeddable Python distributions has been removed. This support was experimental. The official Windows embeddable distributions are missing critical support files that make them difficult to integrate with PyOxidizer.

- The pyembed crate now defines a new OxidizedPythonInterpreterConfig type to configure Python interpreters. The legacy PythonConfig type has been removed.
- Various run\_\* functions on pyembed::MainPythonInterpreter have been moved to standalone functions in the pyembed crate. The run\_as\_main() function (which is called by the default Rust program that is generated) will always call Py\_RunMain() and finalize the interpreter. See the extensive crate docs for move.
- Python resources data in the pyembed crate is no longer annotated with the 'static lifetime. Instances of PythonConfig and OxidizedPythonInterpreterConfig must now be annotated with a lifetime for the resources data they hold such that Rust lifetimes can be enforced.
- The type of the custom Python importer has been renamed from PyOxidizerFinder to OxidizedFinder.
- The name of the module providing our custom importer has been renamed from \_pyoxidizer\_importer to oxidized\_importer.
- Minimum Rust version changed from 1.36 to 1.40 to allow for upgrading various dependencies to modern versions.
- Windows static extension building is possibly broken due to changes to distutils. However, since we changed the default configuration to not use this build mode, we've deemed this potential regression acceptable for the 0.8 release. If it exists, it will hopefully be fixed in the 0.9 release.
- The pip\_install(), read\_package\_root(), read\_virtualenv() and setup\_py\_install() methods of the PythonDistribution Starlark type have been moved to the PythonExecutable type. Existing Starlark config files will need to change references accordingly (often by replacing dist. with exe.).
- The PythonDistribution.extension\_modules() Starlark function no longer accepts arguments filter and preferred\_variants. The function now returns every extension in the distribution. The reasons for this change were to make code simpler and the justification for removing it was rather weak. Please file an issue if this feature loss affects you.
- The PythonInterpreterConfig Starlark type now interally has most of its fields defined to None by default instead of their default values.

 PythonExecutable.add_filesystem_relative_package_distribution_resource();
 PythonExecutable.add_in_memory_extension_module();
                                                               PythonExecutable.
 add_filesystem_relative_extension_module();
                                                               PythonExecutable.
```

add\_in\_memory\_python\_resource();PythonExecutable.add\_filesystem\_relative\_python\_resource
PythonExecutable.add\_in\_memory\_python\_resources(); PythonExecutable.
add\_filesystem\_relative\_python\_resources().

- The Starlark PythonDistribution.to\_python\_executable() method no longer accepts the arguments extension\_module\_filter, preferred\_extension\_module\_variants, include\_sources, include\_resources, and include\_test. All of this functionality has been replaced by the optional packaging\_policy, which accepts a PythonPackagingPolicy instance. The new type represents all settings influencing executable building and control over resources added to the executable.
- The Starlark type PythonBytecodeModule has been removed. Previously, this type was internally a request to convert Python module source into bytecode. The introduction of PythonPackagingPolicy and underlying abilities to derive bytecode from a Python source module instance when adding that resource type rendered this Starlark type redundant. There may still be the need for a Starlark type to represent actual Python module bytecode (not derived from source code at build/packaging time). However, this functionality did not exist before so the loss of this type is not a loss in functionality.
- The Starlark methods PythonExecutable.add\_python\_resource() and PythonExecutable. add\_python\_resources() no longer accept the arguments add\_source\_module, add\_bytecode\_module, and optimize\_level. Instead, set various add\_\* attributes on resource instances being passed into the methods to influence what happens when they are added.
- The Starlark PythonExecutable.add\_python\_module\_source(), methods PythonExecutable.add\_python\_module\_bytecode(), PythonExecutable. add\_python\_package\_resource(), PythonExecutable.add\_python\_package\_distribution\_resource and PythonExecutable.add\_python\_extension\_module() have been removed. The remaining PythonExecutable.add\_python\_resource() and PythonExecutable. add\_python\_resources () methods are capable of handling all resource types and should be used. Previous functionality available via argument passing on these methods can be accomplished by setting add\_\* attributes on individual Python resource objects.
- The Starlark type PythonSourceModule has been renamed to PythonModuleSource.
- Serialized Python resources no longer rely on the flavor field to influence how they are loaded at run-time. Instead, the new is\_\* fields expressing individual type affinity are used. The flavor attributes from the OxidizedResource Python type has been removed since it does nothing.
- The packed resources data format version has been changed from 1 to 2. The parser has dropped support for reading version 1 files. Packed resources blobs will need to be written and read by the same version of the Rust crate to be compatible.
- The autogenerated Rust file containing the Python interpreter configuration now pyembed::OxidizedPythonInterpreterConfig emits instance instead а of pyembed::PythonConfig. The new type is more powerful and what is actually used to initialize an embedded Python interpreter.
- The concept of a *resources policy* in Starlark has now largely been replaced by attributes denoting valid locations for resources.
- **oxidized\_importer.OxidizedResourceCollector.\_\_init\_\_() now** accepts an allowed\_locations **argument instead** of policy.
- The PythonInterpreterConfig() constructor has been removed. Instances of this Starlark type are now created via PythonDistribution.make\_python\_interpreter\_config(). In addition, instances are mutated by setting attributes rather than passing perhaps dozens of arguments to a constructor function.
- The default build configuration for Windows no longer forces extension modules to be loaded from memory and materializes some extension modules as standalone files. This was done because some some extension modules weren't working when loaded from memory and the configuration caused lots of problems in

the wild. The new default should be much more user friendly. To use the old settings, construct a custom PythonPackagingPolicy and set allow\_in\_memory\_shared\_library\_loading = True and resources\_location\_fallback = None.

#### **New Features**

- Python distributions upgraded to CPython 3.8.6.
- CPython 3.9 distributions are now supported by passing python\_version="3.9" to the default\_python\_distribution() Starlark function. CPython 3.8 is the default distribution version.
- Embedded Python interpreters are now managed via the new apis defined by PEP-587. This gives us much more control over the configuration of interpreters.
- A FileManifest Starlark instance will now have its default pyoxidizer run executable set to the last added Python executable. Previously, it would only have a run target if there was a single executable file in the FileManifest. If there were multiple executables or executable files (such as Python extension modules) a run target would not be available and pyoxidizer run would do nothing.
- Default Python distributions upgraded to version 5 of the standalone distribution format. This new format advertises much more metadata about the distribution, enabling PyOxidizer to take fewer guesses about how the distribution works and will help enable more features over time.
- The pyembed crate now exposes a new OxidizedPythonInterpreterConfig type (and associated types) allowing configuration of every field supported by Python's interpreter configuration API.
- Resources data loaded by the pyembed crate can now have a non-'static lifetime. This means that resources data can be more dynamically obtained (e.g. by reading a file). PyOxidizer does not yet support such mechanisms, however.
- OxidizedFinder instances can now be *constructed from Python code*. This means that a Python application can instantiate and install its own oxidized module importer.
- The resources indexed by OxidizedFinder instances are now representable to Python code as OxidizedResource instances. These types can be created, queried, and mutated by Python code. See *OxidizedResource* for the API.
- OxidizedFinder instances can now have custom OxidizedResource instances registered against them. This means Python code can collect its own Python modules and register them with the importer. See *add\_resource(self, resource: OxidizedResource)* for more.
- OxidizedFinder instances can now serialize indexed resources out to a bytes. The serialized data can be loaded into a separate OxidizedFinder instance, perhaps in a different process. This facility enables the creation and reuse of packed resources data structures without having to use pyoxidizer to collect Python resources data.
- The types returned by OxidizedFinder.find\_distributions() now implement entry\_points, allowing *entry points* to be discovered.
- The types returned by OxidizedFinder.find\_distributions() now implement requires, allowing package requirements to be discovered.
- OxidizedFinder is now able to load Python modules when only source code is provided. Previously, it required that bytecode be available.
- OxidizedFinder now implements iter\_modules(). This enables pkgutil.iter\_modules() to return modules serviced by OxidizedFinder.
- The PythonModuleSource Starlark type now exposes module source code via the source attribute.

- The PythonExecutable Starlark type now has a make\_python\_module\_source() method to allow construction of PythonModuleSource instances.
- The PythonModuleSource Starlark type now has attributes add\_include, add\_location, add\_location\_fallback, add\_source, add\_bytecode\_optimization\_level\_zero, add\_bytecode\_optimization\_level\_one, and add\_bytecode\_optimization\_level\_two to influence what happens when instances are added to to binaries.
- The Starlark methods for adding Python resources now accept an optional location argument for controlling the load location of the resource. This functionality replaces the prior functionality provided by location-specific APIs such as PythonExecutable.add\_in\_memory\_python\_resource(). The following methods gained this argument: PythonExecutable. add\_python\_module\_source(); PythonExecutable.add\_python\_module\_bytecode(); PythonExecutable.add\_python\_package\_resource(); PythonExecutable. add\_python\_package\_distribution\_resource(); PythonExecutable. add\_python\_extension\_module(); PythonExecutable.add\_python\_resource(); PythonExecutable.add\_python\_resources().
- Starlark now has a PythonPackagingPolicy type to represent the collection of settings influencing how Python resources are packaged into binaries.
- The PythonDistribution Starlark type has gained a make\_packaging\_policy() method for obtaining the default PythonPackagingPolicy for that distribution.
- The PythonPackagingPolicy.register\_resource\_callback() method can be used to register a Starlark function that will be called whenever resources are created. The callback allows a single function to inspect and manipulate resources as they are created.
- Starlark types representing Python resources now expose an is\_stdlib attribute denoting whether they came from the Python distribution.
- The new PythonExecutable.pip\_download() method will run pip download to obtain Python wheels for the requested package(s). Those wheels will then be parsed for Python resources, which can be added to the executable.
- The Starlark function default\_python\_distribution() now accepts a python\_version argument to control the *X*.*Y* version of Python to use.
- The PythonPackagingPolicy Starlark type now exposes a flag to control whether shared libraries can be loaded from memory.
- The PythonDistribution Starlark type now has a make\_python\_interpreter\_config() method to obtain instances of PythonInterpreterConfig that are appropriate for that distribution.
- PythonInterpreterConfig Starlark types now expose attributes to query and mutate state. Nearly every setting exposed by Python's initialization API can be set.

#### **Bug Fixes**

- Fixed potential process crash due to illegal memory access when loading Python bytecode modules from the filesystem.
- Detection of Python bytecode files based on registered suffixes and cache tags is now more robust. Before, it was possible for modules to get picked up having the cache tag (e.g. cpython-38) in the module name.
- In the custom Python importer, read\_text() of distributions returned from find\_distributions() now returns None on unknown file instead of raising IOError. This matches the behavior of importlib. metadata.
- The pyembed Rust project build script now reruns when the source Starlark file changes.

- Some Python resource types were improperly installed in the wrong relative directory. The buggy behavior has been fixed.
- Python extension modules and their shared library dependencies loaded from the filesystem should no longer have the library file suffix stripped when materialized on the filesystem.
- On Windows, the sqlite module can now be imported. Before, the system for serializing resources thought that sqlite was a shared library and not a Python module.
- The build script of the pyoxidizer crate now uses the git2 crate to try to resolve the Git commit instead of relying on the git command. This should result in fewer cases where the commit was being identified as unknown.
- \$ORIGIN is properly expanded in sys.path. (This was a regression during the development of version 0.8 and is not a regression from the 0.7 release.)

#### **Other Relevant Changes**

- The registration of the custom Python importer during interpreter initialization no longer relies on running custom frozen bytecode for the importlib.\_bootstrap\_external Python module. This simplifies packaging and interpreter configuration a bit.
- Packaging documentation now gives more examples on how to use available Starlark packaging methods.
- The modified distutils files used when building statically linked extensions have been upgraded to those based on Python 3.8.3.
- The default pyoxidizer.bzl now has comments for the packaging\_policy argument to PythonDistribution.to\_python\_executable().
- The default pyoxidizer.bzl now uses add\_python\_resources() instead of add\_in\_memory\_python\_resources().
- The Rust Starlark crate was upgraded from version 0.2 to 0.3. There were numerous changes as part of this upgrade. While we think behavior should be mostly backwards compatible, there may be some slight changes in behavior. Please file issues if any odd behavior or regressions are observed.
- The configuration documentation was reorganized. The unified document for the complete API document (which was the largest single document) has been split into multiple documents.
- The serialized data structure for representing Python resources metadata and its data now allows resources to identify as multiple types. For example, a single resource can contain both Python module source/bytecode and a shared library.
- pyoxidizer --version now prints verbose information about where PyOxidizer was installed, what Git commit was used, and how the pyembed crate will be referenced. This should make it easier to help debug installation issues.
- The autogenerated/default Starlark configuration file now uses the install target as the default build/run target. This allows extra files required by generated binaries to be available and for built binaries to be usable.

## 13.2.3 0.7.0

Released April 9, 2020.

#### **Backwards Compatibility Notes**

- Packages imported from memory using PyOxidizer now set \_\_path\_\_ with a value formed by joining the current executable's path with the package name. This mimics the behavior of zipimport.
- Resolved Python resource names have changed behavior. See the note in the bug fixes section below.
- The PythonDistribution.to\_python\_executable() Starlark method has added a packaging\_policy named argument as its 2nd argument / 1st named argument. If you were affected by this, you should add argument names to all arguments passed to this method.
- The default Rust project for built executables now builds executables such that dynamic symbols are exported from the executable. This change is necessary in order to support executables loading Python extension modules, which are shared libraries which need access to Python symbols defined in executables.
- The PythonResourceData Starlark type has been renamed to PythonPackageResource.
- The PythonDistribution.resources\_data() Starlark method has been renamed to PythonDistribution.package\_resources().
- The PythonExecutable.to\_embedded\_data() Starlark method has been renamed to PythonExecutable.to\_embedded\_resources().
- The PythonEmbeddedData Starlark type has been renamed to PythonEmbeddedResources.
- The format of Python resource data embedded in binaries has been completely rewritten. The separate modules and resource data structures have been merged into a single data structure. Embedded resources data can now express more primitives such as package distribution metadata and different bytecode optimization levels.
- The pyembed crate now has a dev dependency on the pyoxidizer crate in order to run tests.

#### **Bug Fixes**

- PyOxidizer's importer now always sets \_\_path\_\_ on imported packages in accordance with Python's stated behavior (#51).
- The mechanism for resolving Python resource files from the filesystem has been rewritten. Before, it was possible for files like package/resources/foo.txt to be normalized to a (package, resource\_name) tuple of (*package, resources.foo.txt*), which was weird and not compatible with Python's resource loading mechanism. Resources in sub-directories should no longer encounter munging of directory separators to .. In the above example, the resource path will now be expressed as (package, resources/foo.txt).
- Certain packaging actions are only performed once during building instead of twice. The user-visible impact of this change is that some duplicate log messages no longer appear.
- Added a missing ) for *add\_python\_resources()* in auto-generated *pyoxidizer.bzl* files.

#### **New Features**

- Python resource scanning now recognizes \*.dist-info and \*.egg-info directories as package distribution metadata. Files within these directories are exposed to Starlark as *PythonPackageDistributionResource* instances. These resources can be added to the embedded resources payload and made available for loading from memory or the filesystem, just like any other resource. The custom Python importer implements get\_distributions() and returns objects that expose package distribution files. However, functionality of the returned *distribution* objects is not yet complete. See *importlib.metadata Compatibility* for details.
- The custom Python importer now implements get\_data (path), allowing loading of resources from filesystem paths (#139).

- The PythonDistribution.to\_python\_executable() Starlark method now accepts a packaging\_policy argument to control a policy and default behavior for resources on the produced executable. Using this argument, it is possible to control how resources should be materialized. For example, you can specify that resources should be loaded from memory if supported and from the filesystem if not. The argument can also be used to materialize the Python standard library on the filesystem, like how Python distributions typically work.
- Python resources can now be installed next to built binaries using the new Starlark functions PythonExecutable.add filesystem relative module source(), PythonExecutable. add\_filesystem\_relative\_module\_bytecode(), PythonExecutable. add\_filesystem\_relative\_package\_resource(), PythonExecutable. add\_filesystem\_relative\_extension\_module(), PythonExecutable. add\_filesystem\_relative\_python\_resource(), PythonExecutable. add\_filesystem\_relative\_package\_distribution\_resource(), and PythonExecutable.add\_filesystem\_relative\_python\_resources(). Unlike adding Python resources to FileManifest instances, Python resources added this way have their metadata serialized into the built executable. This allows the special Python module importer present in built binaries to service the import request without going through Python's default filesystem-based importer. Because metadata for the file-based Python resources is *frozen* into the application, Python has to do far less work at run-time to load resources, making operations faster. Resources loaded from the filesystem in this manner have attributes like \_\_\_\_\_file\_\_\_, \_\_\_cached\_\_\_\_, and \_\_\_path\_\_\_ set, emulating behavior of the default Python importer. The custom import now also implements the importlib.abc.ExecutionLoader interface.
- Windows binaries can now import extension modules defined as shared libraries (e.g. .pyd files) from memory. PyOxidizer will detect .pyd files during packaging and embed them into the binary as resources. When the module is imported, the extension module/shared library is loaded from memory and initialized. This feature enables PyOxidizer to package pre-built extension modules (e.g. from Windows binary wheels published on PyPI) while still maintaining the property of a (mostly) self-contained executable.
- Multiple bytecode optimization levels can now be embedded in binaries. Previously, it was only possible to embed bytecode for a given module at a single optimization level.
- The default\_python\_distribution() Starlark function now accepts values standalone\_static and standalone\_dynamic to specify a *standalone* distribution that is either statically or dynamically linked.
- Support for parsing version 4 of the PYTHON.json distribution descriptor present in standalone Python distribution archives.
- Default Python distributions upgraded to CPython 3.7.7.

#### **Other Relevant Changes**

- The directory for downloaded Python distributions in the build directory now uses a truncated SHA-256 hash instead of the full hash to help avoid path length limit issues (#224).
- The documentation for the pyembed crate has been moved out of the Sphinx documentation and into the Rust crate itself. Rendered docs can be seen by following the *Documentation* link at https://crates.io/crates/pyembed or by running cargo doc from a source checkout.

## 13.2.4 0.6.0

Released February 12, 2020.

#### **Backwards Compatibility Notes**

- The default\_python\_distribution() Starlark function now accepts a flavor argument denoting the distribution flavor.
- The pyembed crate no longer includes the auto-generated default configuration file. Instead, it is consumed by the application that instantiates a Python interpreter.
- Rust projects for the main executable now utilize and require a Cargo build script so metadata can be passed from pyembed to the project that is consuming it.
- The pyembed crate is no longer added to created Rust projects. Instead, the generated Cargo.toml will reference a version of the pyembed crate identical to the PyOxidizer version currently running. Or if pyoxidizer is running from a Git checkout of the canonical PyOxidizer Git repository, a local filesystem path will be used.
- The fields of EmbeddedPythonConfig and pyembed::PythonConfig have been renamed and reordered to align with Python 3.8's config API naming. This was done for the Starlark type in version 0.5. We have made similar changes to 0.6 so naming is consistent across the various types.

#### **Bug Fixes**

• Module names without a . are now properly recognized when scanning the filesystem for Python resources and a package allow list is used (#223). Previously, if filtering scanned resources through an explicit list of allowed packages, the top-level module/package without a dot in its full name would not be passed through the filter.

#### **New Features**

- The PythonDistribution () Starlark function now accepts a flavor argument to denote the distribution type. This allows construction of alternate distribution types.
- The default\_python\_distribution() Starlark function now accepts a flavor argument which can be set to windows\_embeddable to return a distribution based on the zip file distributions published by the official CPython project.
- The pyembed crate and generated Rust projects now have various build-mode-\* feature flags to control how build artifacts are built. See *Rust Projects* for more.
- The pyembed crate can now be built standalone, without being bound to a specific PyOxidizer configuration.
- The register\_target() Starlark function now accepts an optional default\_build\_script argument to define the default target when evaluating in *Rust build script* mode.
- The pyembed crate now builds against published cpython and python3-sys crates instead of a a specific Git commit.
- Embedded Python interpreters can now be configured to run a file specified by a filename. See the run\_file argument of *PythonInterpreterConfig*.

#### **Other Relevant Changes**

- Rust internals have been overhauled to use traits to represent various types, namely Python distributions. The goal is to allow different Python distribution flavors to implement different logic for building binaries.
- The pyembed crate's build.rs has been tweaked so it can support calling out to pyoxidizer. It also no longer has a build dependency on pyoxidizer.

## 13.2.5 0.5.1

Released January 26, 2020.

#### **Bug Fixes**

- Fixed bad Starlark example for building black in docs.
- Remove resources attached to packages that don't exist. (This was a regression in 0.5.)
- Warn on failure to annotate a package. (This was a regression in 0.5.)
- Building embedded Python resources now emits warnings when \_\_\_\_\_\_\_\_ is seen. (This was a regression in 0.5.)
- Missing parent packages are now automatically added when constructing embedded resources. (This was a regression in 0.5.)

## 13.2.6 0.5.0

Released January 26, 2020.

#### **General Notes**

This release of PyOxidizer is significant rewrite of the previous version. The impetus for the rewrite is to transition from TOML to Starlark configuration files. The new configuration file format should allow vastly greater flexibility for building applications and will unlock a world of new possibilities.

The transition to Starlark configuration files represented a shift from static configuration to something more dynamic. This required refactoring a ton of code.

As part of refactoring code, we took the opportunity to shore up lots of the code base. PyOxidizer was the project author's first real Rust project and a lot of bad practices (such as use of *.unwrap()*/panics) were prevalent. The code mostly now has proper error handling. Another new addition to the code is unit tests. While coverage still isn't great, we now have tests performing meaningful packaging activities. So regressions should hopefully be less common going forward.

Because of the scale of the rewritten code in this release, it is expected that there are tons of bugs of regressions. This will likely be a transitional release with a more robust release to follow.

#### **Backwards Compatibility Notes**

- Support for building distributions/installers has been temporarily dropped.
- Support for installing license files has been temporarily dropped.
- Python interpreter configuration setting names have been changed to reflect names from Python 3.8's interpreter initialization API.
- .egg-info directories are now ignored when scanning for Python resources on the filesystem (matching the behavior for .dist-info directories).
- The pyoxidizer init sub-command has been renamed to init-rust-project.
- The pyoxidizer app-path sub-command has been removed.
- Support for building distributions has been removed.

- The minimum Rust version to build has been increased from 1.31 to 1.36. This is mainly due to requirements from the starlark crate. We could potentially reduce the minimum version requirements again with minimal changes to 3rd party crates.
- PyOxidizer configuration files are now Starlark instead of TOML files. The default file name is pyoxidizer. bzl instead of pyoxidizer.toml. All existing configuration files will need to be ported to the new format.

#### **Bug Fixes**

- The repl run mode now properly exits with a non-zero exit code if an error occurs.
- Compiled C extensions now properly honor the ext\_package argument passed to setup(), resulting in extensions which properly have the package name in their extension name (#26).

#### **New Features**

- A *glob()* function has been added to config files to allow referencing existing files on the filesystem.
- The in-memory MetaPathFinder now implements find\_module().
- A pyoxidizer init-config-file command has been implemented to create just a pyoxidizer. bzl configuration file.
- A pyoxidizer python-distribution-info command has been implemented to print information about a Python distribution archive.
- The EmbeddedPythonConfig() config function now accepts a legacy\_windows\_stdio argument to control the value of Py\_LegacyWindowsStdioFlag (#190).
- The EmbeddedPythonConfig() config function now accepts a legacy\_windows\_fs\_encoding argument to control the value of Py\_LegacyWindowsFSEncodingFlag.
- The EmbeddedPythonConfig() config function now accepts an isolated argument to control the value of Py\_IsolatedFlag.
- The EmbeddedPythonConfig() config function now accepts a use\_hash\_seed argument to control the value of Py\_HashRandomizationFlag.
- The EmbeddedPythonConfig() config function now accepts an inspect argument to control the value of Py\_InspectFlag.
- The EmbeddedPythonConfig() config function now accepts an interactive argument to control the value of Py\_InteractiveFlag.
- The EmbeddedPythonConfig() config function now accepts a quiet argument to control the value of Py\_QuietFlag.
- The EmbeddedPythonConfig() config function now accepts a verbose argument to control the value of Py\_VerboseFlag.
- The EmbeddedPythonConfig() config function now accepts a parser\_debug argument to control the value of Py\_DebugFlag.
- The EmbeddedPythonConfig() config function now accepts a bytes\_warning argument to control the value of Py\_BytesWarningFlag.
- The Stdlib() packaging rule now now accepts an optional excludes list of modules to ignore. This is useful for removing unnecessary Python packages such as distutils, pip, and ensurepip.
- The PipRequirementsFile() and PipInstallSimple() packaging rules now accept an optional extra\_env dict of extra environment variables to set when invoking pip install.

• The PipRequirementsFile() packaging rule now accepts an optional extra\_args list of extra command line arguments to pass to pip install.

#### **Other Relevant Changes**

• PyOxidizer no longer requires a forked version of the rust-cpython project (the python3-sys and cpython crates. All changes required by PyOxidizer are now present in the official project.

## 13.2.7 0.4.0

Released October 27, 2019.

#### **Backwards Compatibility Notes**

• The setup-py-install packaging rule now has its package\_path evaluated relative to the PyOxidizer config file path rather than the current working directory.

#### **Bug Fixes**

- Windows now explicitly requires dynamic linking against msvort. Previously, this wasn't explicit. And sometimes linking the final executable would result in unresolved symbol errors because the Windows Python distributions used external linkage of CRT symbols and for some reason Cargo wasn't dynamically linking the CRT.
- Read-only files in Python distributions are now made writable to avoid future permissions errors (#123).
- In-memory InspectLoader.get\_source() implementation no longer errors due to passing a memoryview to a function that can't handle it (#134).
- In-memory ResourceReader now properly handles multiple resources (#128).

#### **New Features**

- Added an app-path command that prints the path to a packaged application. This command can be useful for tools calling PyOxidizer, as it will emit the path containing the packaged files without forcing the caller to parse command output.
- The setup-py-install packaging rule now has an excludes option that allows ignoring specific packages or modules.
- .py files installed into app-relative locations now have corresponding .pyc bytecode files written.
- The setup-py-install packaging rule now has an extra\_global\_arguments option to allow passing additional command line arguments to the setup.py invocation.
- Packaging rules that invoke pip or setup.py will now set a PYOXIDIZER=1 environment variable so Python code knows at packaging time whether it is running in the context of PyOxidizer.
- The setup-py-install packaging rule now has an extra\_env option to allow passing additional environment variables to setup.py invocations.
- [[embedded\_python\_config]] now supports a sys\_frozen flag to control setting sys.frozen = True.

- [[embedded\_python\_config]] now supports a sys\_meipass flag to control setting sys.\_MEIPASS = <exe directory>.
- Default Python distribution upgraded to 3.7.5 (from 3.7.4). Various dependency packages also upgraded to latest versions.

#### **All Other Relevant Changes**

• Built extension modules marked as app-relative are now embedded in the final binary rather than being ignored.

## 13.2.8 0.3.0

Released on August 16, 2019.

#### **Backwards Compatibility Notes**

- The pyembed::PythonConfig struct now has an additional extra\_extension\_modules field.
- The default musl Python distribution now uses LibreSSL instead of OpenSSL. This should hopefully be an invisible change.
- Default Python distributions now use CPython 3.7.4 instead of 3.7.3.
- Applications are now built into directories named apps/<app\_name>/<target>/<build\_type> rather than apps/<app\_name>/<build\_type>. This enables builds for multiple targets to coexist in an application's output directory.
- The program\_name field from the [[embedded\_python\_config]] config section has been removed. At run-time, the current executable's path is always used when calling Py\_SetProgramName().
- The format of embedded Python module data has changed. The pyembed crate and pyoxidizer versions must match exactly or else the pyembed crate will likely crash at run-time when parsing module data.

#### **Bug Fixes**

- The libedit extension variant for the readline extension should now link on Linux. Before, attempting to link a binary using this extension variant would result in missing symbol errors.
- The setup-py-install [[packaging\_rule]] now performs actions to appease setuptools, thus allowing installation of packages using setuptools to (hopefully) work without issue (#70).
- The virtualenv [[packaging\_rule]] now properly finds the site-packages directory on Windows (#83).
- The filter-include [[packaging\_rule]] no longer requires both files and glob\_files be defined (#88).
- import ctypes now works on Windows (#61).
- The in-memory module importer now implements get\_resource\_reader() instead of get\_resource\_loader(). (The CPython documentation steered us in the wrong direction https://bugs.python.org/issue37459.)
- The in-memory module importer now correctly populates \_\_package\_\_ in more cases than it did previously. Before, whether a module was a package was derived from the presence of a foo.bar module. Now, a module will be identified as a package if the file providing it is named \_\_init\_\_. This more closely matches the behavior of Python's filesystem based importer. (#53)

#### **New Features**

- The default Python distributions have been updated. Archives are generally about half the size from before. Tcl/tk is included in the Linux and macOS distributions (but PyOxidizer doesn't yet package the Tcl files).
- Extra extension modules can now be registered with PythonConfig instances. This can be useful for having the application embedding Python provide its own extension modules without having to go through Python build mechanisms to integrate those extension modules into the Python executable parts.
- Built applications now have the ability to detect and use terminfo databases on the execution machine. This allows applications to interact with terminals properly. (e.g. the backspace key will now work in interactive pdb sessions). By default, applications on non-Windows platforms will look for terminfo databases at well-known locations and attempt to load them.
- Default Python distributions now use CPython 3.7.4 instead of 3.7.3.
- A warning is now emitted when a Python source file contains \_\_\_\_\_file\_\_\_. This should help trace down modules using \_\_\_\_\_\_file\_\_\_.
- Added 32-bit Windows distribution.
- New pyoxidizer distribution command for producing distributable artifacts of applications. Currently supports building tar archives and .msi and .exe installers using the WiX Toolset.
- Libraries required by C extensions are now passed into the linker as library dependencies. This should allow C extensions linked against libraries to be embedded into produced executables.
- pyoxidizer --verbose will now pass verbose to invoked pip and setup.py scripts. This can help debug what Python packaging tools are doing.

#### **All Other Relevant Changes**

• The list of modules being added by the Python standard library is no longer printed during rule execution unless --verbose is used. The output was excessive and usually not very informative.

## 13.2.9 0.2.0

Released on June 30, 2019.

#### **Backwards Compatibility Notes**

• Applications are now built into an apps/<appname>/(debug|release) directory instead of apps/ <appname>. This allows debug and release builds to exist side-by-side.

#### **Bug Fixes**

- Extracted .egg directories in Python package directories should now have their resources detected properly and not as Python packages with the name \*.egg.
- site-packages directories are now recognized as Python resource package roots and no longer have their contents packaged under a site-packages Python package.

#### **New Features**

- Support for building and embedding C extensions on Windows, Linux, and macOS in many circumstances. See *Native Extension Modules* for support status.
- pyoxidizer init now accepts a --pip-install option to pre-configure generated pyoxidizer. toml files with packages to install via pip. Combined with the --python-code option, it is now possible to create pyoxidizer.toml files for a ready-to-use Python application!
- pyoxidizer now accepts a --verbose flag to make operations more verbose. Various low-level output is no longer printed by default and requires --verbose to see.

#### **All Other Relevant Changes**

- Packaging now automatically creates empty modules for missing parent packages. This prevents a module from being packaged without its parent. This could occur with *namespace packages*, for example.
- pip-install-simple rule now passes -- no-binary :all: to pip.
- Cargo packages updated to latest versions.

## 13.2.10 0.1.3

Released on June 29, 2019.

#### **Bug Fixes**

- Fix Python refcounting bug involving call to PyImport\_AddModule() when mode = module evaluation mode is used. The bug would likely lead to a segfault when destroying the Python interpreter. (#31)
- Various functionality will no longer fail when running pyoxidizer from a Git repository that isn't the canonical PyOxidizer repository. (#34)

#### **New Features**

- pyoxidizer init now accepts a --python-code option to control which Python code is evaluated in the produced executable. This can be used to create applications that do not run a Python REPL by default.
- pip-install-simple packaging rule now supports excludes for excluding resources from packaging. (#21)
- pip-install-simple packaging rule now supports extra\_args for adding parameters to the pip install command. (#42)

#### **All Relevant Changes**

- Minimum Rust version decreased to 1.31 (the first Rust 2018 release). (#24)
- Added CI powered by Azure Pipelines. (#45)
- Comments in auto-generated pyoxidizer.toml have been tweaked to improve understanding. (#29)

## 13.2.11 0.1.2

Released on June 25, 2019.

#### **Bug Fixes**

- Honor HTTP\_PROXY and HTTPS\_PROXY environment variables when downloading Python distributions. (#15)
- Handle BOM when compiling Python source files to bytecode. (#13)

#### **All Relevant Changes**

• pyoxidizer now verifies the minimum Rust version meets requirements before building.

## 13.2.12 0.1.1

Released on June 24, 2019.

#### **Bug Fixes**

• pyoxidizer binaries built from crates should now properly refer to an appropriate commit/tag in PyOxidizer's canonical Git repository in auto-generated Cargo.toml files. (#11)

## 13.2.13 0.1

Released on June 24, 2019. This is the initial formal release of PyOxidizer. The first pyoxidizer crate was published to crates.io.

#### **New Features**

- Support for building standalone, single file executables embedding Python for 64-bit Windows, macOS, and Linux.
- Support for importing Python modules from memory using zero-copy.
- Basic Python packaging support.
- Support for jemalloc as Python's memory allocator.
- pyoxidizer CLI command with basic support for managing project lifecycle.

# CHAPTER 14

# **Technical Notes**

# 14.1 CPython Initialization

Most code lives in pylifecycle.c.

Call tree with Python 3.7:

```
``Py_Initialize()``
  `Py_InitializeEx()``
     _Py_InitializeFromConfig(_PyCoreConfig config)``
       _Py_InitializeCore(PyInterpreterState, _PyCoreConfig)``
       Sets up allocators.
       ``_Py_InitializeCore_impl(PyInterpreterState, _PyCoreConfig)``
         Does most of the initialization.
         Runtime, new interpreter state, thread state, GIL, built-in types,
         Initializes sys module and sets up sys.modules.
         Initializes builtins module.
          ``_PyImport_Init()``
           Copies ``interp->builtins`` to ``interp->builtins_copy``.
         ``_PyImportHooks_Init()`
           Sets up ``sys.meta_path``, ``sys.path_importer_cache``,
           ``sys.path_hooks`` to empty data structures.
         ``initimport()``
           ``PyImport_ImportFrozenModule("_frozen_importlib")``
           ``PyImport_AddModule("_frozen_importlib")`
           ``interp->importlib = importlib`
           ``interp->import_func = interp->builtins.__import__``
           ``PyInit__imp()`
            Initializes ``_imp`` module, which is implemented in C.
           ``sys.modules["_imp"} = imp`
           ``importlib._install(sys, _imp)``
           ``_PyImportZip_Init()`
     ``_Py_InitializeMainInterpreter(interp, _PyMainInterpreterConfig)``
```

(continues on next page)

(continued from previous page)

```
``_PySys_EndInit()``
  ``sys.path = XXX``
  ``sys.executable = XXX``
  ``sys.prefix = XXX``
  ``sys.base_prefix = XXX``
  ``sys.exec_prefix = XXX``
  ``sys.base_exec_prefix = XXX``
  ``sys.argv = XXX`
  ``sys.warnoptions = XXX``
  ``sys._xoptions = XXX`
  ``sys.flags = XXX``
  ``sys.dont_write_bytecode = XXX``
``initexternalimport()``
  ``interp->importlib._install_external_importers()``
``initfsencoding()``
  `_PyCodec_Lookup(Py_FilesystemDefaultEncoding)``
      _PyCodecRegistry_Init()``
      ``interp->codec_search_path = []``
      ``interp->codec_search_cache = {}``
      ``interp->codec_error_registry = {}``
      # This is the first non-frozen import during startup.
      ``PyImport_ImportModuleNoBlock("encodings")`
    ``interp->codec_search_cache[codec_name]`
    ``for p in interp->codec_search_path: p[codec_name]``
``initsigs()``
``add_main_module()``
  ``PyImport_AddModule("___main___")``
``init_sys_streams()``
  ``PyImport_ImportModule("encodings.utf_8")``
  ``PyImport_ImportModule("encodings.latin_1")``
  ``PyImport_ImportModule("io")``
  Consults ``PYTHONIOENCODING`` and gets encoding and error mode.
  Sets up ``sys.__stdin__``, ``sys.__stdout__``, ``sys.__stderr__`
Sets warning options.
Sets ``_PyRuntime.initialized``, which is what ``Py_IsInitialized()``
returns.
 `initsite()``
  ``PyImport_ImportModule("site")``
```

# 14.2 CPython Importing Mechanism

Lib/importlib defines importing mechanisms and is 100% Python.

Programs/\_freeze\_importlib.c is a program that takes a path to an input .py file and path to output .h file. It initializes a Python interpreter and compiles the .py file to marshalled bytecode. It writes out a .h file with an inline const unsigned char \_Py\_M\_\_importlib array containing bytecode.

Lib/importlib/\_bootstrap\_external.py compiled to Python/importlib\_external.h with \_Py\_M\_\_importlib\_external[].

Lib/importlib/\_bootstrap.py compiled to Python/importlib.h with \_Py\_M\_\_importlib[].

Python/frozen.c has \_PyImport\_FrozenModules[] effectively mapping \_frozen\_importlib to importlib.\_bootstrap and \_frozen\_importlib\_external to importlib. \_bootstrap\_external. initimport() calls PyImport\_ImportFrozenModule("\_frozen\_importlib"), effectively import importlib.\_bootstrap. Module import doesn't appear to have meaningful side-effects.

importlib.\_bootstrap.\_\_import\_\_ is installed as interp->import\_func.

C implemented \_imp module is initialized.

importlib.\_bootstrap.\_install(sys, \_imp is called. Calls \_setup(sys, \_imp) and adds
BuiltinImporter and FrozenImporter to sys.meta\_path.

\_setup() defines globals \_imp and sys. Populates \_\_name\_\_, \_\_loader\_\_, \_\_package\_\_, \_\_spec\_\_, \_\_path\_\_, \_\_file\_\_, \_\_cached\_\_ on all sys.modules entries. Also loads builtins \_thread, \_warnings, and \_weakref.

Later during interpreter initialization, initexternal() effectively calls importlib.\_bootstrap. \_install\_external\_importers(). This runs import \_frozen\_importlib\_external, which is effectively import importlib.\_bootstrap\_external. This module handle is aliased to importlib. \_bootstrap.\_bootstrap\_external.

importlib.\_bootstrap\_external import doesn't appear to have significant side-effects.

importlib.\_bootstrap\_external.\_install() is called with a reference to importlib. \_bootstrap.\_setup() is called.

importlib.\_bootstrap.\_setup() imports builtins \_io, \_warnings, \_builtins, marshal. Either posix or nt imported depending on OS. Various module-level attributes set defining run-time environment. This includes \_winreg. SOURCE\_SUFFIXES and EXTENSION\_SUFFIXES are updated accordingly.

importlib.\_bootstrap.\_get\_supported\_file\_loaders() returns various loaders. ExtensionFileLoader configured from \_imp.extension\_suffixes(). SourceFileLoader configured from SOURCE\_SUFFIXES. SourcelessFileLoader configured from BYTECODE\_SUFFIXES.

FileFinder.path\_hook() called with all loaders and result added to sys.path\_hooks. PathFinder added to sys.meta\_path.

# 14.4 Modules Imported by site.py

\_collections\_abc \_sitebuiltins \_stat atexit genericpath os os.path posixpath rlcompleter site stat

# 14.5 Random Notes

Frozen importer iterates an array looking for module names. On each item, it calls \_PyUnicode\_EqualToASCIIString(), which verifies the search name is ASCII. Performing an O(n) scan for every frozen module if there are a large number of frozen modules could contribute performance overhead. A better frozen importer would use a map/hash/dict for lookups. This //may// require CPython API breakages, as the PyImport\_FrozenModules data structure is documented as part of the public API and its value could be updated dynamically at run-time.

importlib.\_bootstrap cannot call import because the global import hook isn't registered until after initimport().

importlib.\_bootstrap\_external is the best place to monkeypatch because of the limited run-time functionality available during importlib.\_bootstrap. It's a bit wonky that Py\_Initialize() will import modules from the standard library and it doesn't appear possible to disable this. If site.py is disabled, non-extension builtins are limited to codecs, encodings, abc, and whatever encodings.\* modules are needed by initfsencoding() and init\_sys\_streams().

An attempt was made to freeze the set of standard library modules loaded during initialization. However, the builtin extension importer doesn't set all of the module attributes that are expected of the modules system. The from . import aliases in encodings/\_\_\_init\_\_\_.py is confused without these attributes. And relative imports seemed to have issues as well. One would think it would be possible to run an embedded interpreter with all standard library modules frozen, but this doesn't work.

# 14.6 Desired Changes from Python to Aid PyOxidizer

As part of implementing PyOxidizer, we've encountered numerous shortcomings in Python that have made implementation more difficult. This section attempts to capture those along with our desired outcomes.

### 14.6.1 General Lack of Clear Specifications

PyOxidizer has had to implement a lot of low-level functionality, notably around interpreter initialization and module/resource importing. We have also had to reinvent aspects of packaging so it can be performed in Rust.

Various Python functionality is not defined in specifications. Rather, it is defined by PEPs plus implementations in code. And when there are PEPs, often there isn't a single PEP outlining the clear current state of the world: many PEPs are stated like *builds on top of PEP XYZ*. Often the only canonical source of how something works is the implementation in code. And when there are questions for clarification, it isn't clear whether code or a PEP is wrong because oftentimes there isn't a single PEP that is the canonical source of truth.

It would be highly preferred for Python to publish clear specifications for how various mechanisms work. A PEP would be a diff to a specification (possibly creating a new specification) and a discussion around it. That way there would be a clear specification that can be consulted as the source of truth for how things should behave.

## 14.6.2 \_\_\_\_file\_\_ Ambiguity

It isn't clear whether \_\_\_\_\_\_\_\_ file\_\_\_\_\_ is actually required and what all is derived from existence of \_\_\_\_\_\_\_\_\_. It also isn't clear what \_\_\_\_\_\_\_\_\_ file\_\_\_\_\_ should be set to if it wouldn't be a concrete filesystem path. Can \_\_\_\_\_\_\_\_ file\_\_\_\_\_ be virtual? Can it refer to a binary/archive containing the module?

Semantics of \_\_\_\_\_file\_\_\_ need more clarification.

#### 14.6.3 importlib.metadata Documentation Deficiencies

See https://bugs.python.org/issue38594.

## 14.6.4 importlib Resources Directory Ambiguity

See https://bugs.python.org/issue36128, https://gitlab.com/python-devs/importlib\_resources/issues/58, and https://gitlab.com/python-devs/importlib\_resources/-/issues/90.

## 14.6.5 Standardizing a Python Distribution Format

PyOxidizer consumes Python distributions and repackages them. e.g. it takes an archive containing a Python executable, standard library, support libraries, etc and transforms them into new binaries or distributable artifacts.

There is no standard for representing a Python distribution. This is something that PyOxidizer has had to invent itself via the python-build-standalone project and its PYTHON.json files.

Should Python have a standardized way of describing Python distribution archives and should CPython distribute said distributions, it would make PyOxidizer largely agnostic of the distributor flavor being consumed and allow PyOxidizer (and other Python packaging tools) to more easily target other distribution flavors. e.g. you could swap out CPython for PyPy and tooling largely wouldn't care.

## 14.6.6 Ability to Install Meta Path Importers Before Py\_Initialize()

Py\_Initialize() will import some standard library modules during its execution. It does so using the default meta path importers available to the distribution. This means that standard library modules must come from the filesystem (PathImporter), frozen modules, built-in extension modules, or zip files (via PathImporter).

This restriction prevents importing the entirety of the standard library from the binary containing Python, in effect preventing the use of self-contained executables. PyOxidizer works around this by patching the importlib.\_bootstrap\_and importlib.\_bootstrap\_external source code, compiling that to bytecode, and making said bytecode available as a frozen module. The patched code (which runs as part of Py\_Initialize()) installs a sys.meta\_path importer which imports modules from memory. This solution is extremely hacky, but is necessary to achieve single file executables with all imports serviced from memory.

In order for this to work, PyOxidizer needs a copy of these importlib modules so it can patch them and compile them to bytecode. This is problematic in some cases because e.g. the Windows embeddable Python distributions ship only the bytecode of these modules in a pythonXY.zip file. So PyOxidizer needs to find the source code from another location when consuming these distributions.

But patching the importlib bootstrap modules is hacky itself. It would be better if PyOxidizer didn't need to do this at all. This could be achieved by splitting up the interpreter initialization APIs to give embedding applications the opportunity to muck with sys.meta\_path before any import is performed. It could also be achieved by introducing an initialization config option to somehow inject code at the right point during startup to register the sys.meta\_path importer. This could be done by importing a named module (presumably serviced by the frozen or built-in importer) and having that module run code to modify sys.meta\_path as a side-effect of module evaluation at import time. A variation would be to define a callable in said module to call after the module is importer. Whatever the solution, there needs to be a way to somehow inject a sys.meta\_path importer before any import not serviced by the frozen or built-in importers is performed.

## 14.6.7 Lacking Support for Statically Linked Builds

Python really wants you to be using shared libraries for libpython and extension modules seem to strongly insist on this.

On Windows, there is no official Visual Studio project configuration for static builds. Actually achieving one requires a lot of hacks to the build system (see python-build-standalone project).

There is ~0 support for building statically linked extension modules in packaging tools, from the build step itself all the way up to distribution. (PyOxidizer's approach is to hack distutils to record and save the object files that were compiled and then PyOxidizer manually links these object files into the final binary.)

To achieve a statically linked executable containing libpython and extension modules, you effectively need to build everything from source. And if you want to distribute that executable, you often need to build with special toolchains to ensure binary portability.

There is tons of room for Python to better support static linking. A possible good place to start would be for packaging tools to support building extension modules which don't rely on a dynamic libpython. If artifacts containing the raw object files designed for static linking were made available on PyPI, PyOxidizer could download pre-built binaries and link them directly into an executable or custom libpython. This would avoid having to recompile said extension modules at repackaging time. The compatibility guarantees would likely look a lot like existing binary wheels.

On a related front, it would be nice if musl libc based binary wheels were standardized. There are some concerns about the performance and compatibility of musl libc when it comes to Python. But musl libc is a valid deploy target nonetheless and it would be nice if Python officially supported it. (FWIW the performance concerns seem to stem from memory allocator performance and PyOxidizer supports using jemalloc as the allocator, bypassing this problem.)

## 14.6.8 Windows Embeddable Distributions Missing Functionality

The Windows embeddable zip file distributions of CPython are missing certain functionality.

The distributions do not contain source code for Python modules in the standard library. This means PyOxidizer can't easily bundle sources from these distributions.

The ensurepip module is not present in the distribution. So there is no way to install pip using the distribution itself.

The venv module is also not present in the distribution. So there's no way to create virtualenvs using the distribution itself.

The Python C development headers are not part of the distribution, so even if you install packaging tools, you can't build C extensions.

## 14.6.9 Extension Module / Shared Library Filename Ambiguity

On some platforms, Python extension modules and shared libraries have the same filename extension. e.g. on Linux, both are named foo.so.

PyOxidizer's packaging functionality needs to classify files as specific resource types (source modules, bytecode modules, resource files, extension modules, shared libraries, etc). Because certain file patterns (like .so) are ambiguous, PyOxidizer cannot perform this classification trivially.

It would be much preferred if there were unique file extensions that distinguished Python extension modules from regular shared libraries.

On Windows, this is already the case with the .pyd extension. However, POSIX architectures aren't so fortunate.

## 14.6.10 Ambiguous File Classification

This is somewhat related to the previous section but is more generic.

Python's default path-based importer dynamically looks for presence of various files on the filesystem and loads the first type variant (extension module, bytecode, source, etc) discovered.

PyOxidizer's importer indexes resources during packaging and its import-time resource resolution is static: the type of resource is baked into the definition of the resource.

These approaches are somewhat at odds with each other. The path-based importer is dynamic in nature: it defers answering questions until a specific resource is requested. PyOxidizer's importer is static / pre-compiled: it must classify a resource based on its filename/path so it can bake that knowledge into an immutable data structure. It does not have knowledge of what names will be requested at run-time.

Bridging this divide has revealed various ambiguities and corner cases in the filenames of Python resources.

The Python extension module or shared library ambiguity is described above.

There is also an ambiguity with extra files that aren't part of a known Python package. If you attempt to classify every file in a sys.path directory, it is tempting to classify a file as a Python module (.py, .pyc, or extension module), package resource (importlib.resources), or package metadata (e.g. .dist-info files accessed via importlib.metadata). However, there exists the possibility that a file is not obviously classified as one of these.

For example, a file foo/libfoo.so without the presence of a foo/\_\_init\_\_\_.py file is ambiguous. We could say this is an extension module (foo.libfoo) due to the extension module shared library ambiguity. We could also consider this a package resource foo:libfoo.so or "":foo/libfoo.so. Although the latter case of using an empty string for the package name doesn't make much sense. And we arguably shouldn't consider it a resource of foo because no obvious foo Python package exists!

This is relevant in the real world because various Python packages rely on installing arbitrary files in sys.path directories. For example, numpy installs files like numpy.libs/libz-eb09adld.so.1.2.3, where the numpy.libs directory only contains file extensions \*.so[.\*]. Note that this example is particularly confusing because the directory names in sys.path directories are typically split on . and correspond to Python [sub-]packages.

This ambiguity effectively means that PyOxidizer needs to:

- Determine if a file is a shared library or not (because shared libraries are treated specially and we can't unambiguously identify a shared library from its file extension).
- Examine symbols within shared libraries to see if a Python extension module is present (via presence of PyInit\_\* symbols).
- Preserve *extra* files not present in a Python package. (In the case of numpy, there are no *obvious* links to the shared libraries in the numpy.libs directory: this relative path is encoded within the extension module shared library via e.g. DT\_NEEDED.)

The most robust mitigation to this ambiguity is for all files associated with an installable Python package/distribution to be annotated with their type and for Python package installers to refuse to process files that aren't identified. This could be achieved by having a .dist-info/ file annotating the *role* of each file.

## 14.6.11 Push Harder for Wheels

Wheels are superior for Python packaging distribution because they are more *static* and follow a finite set of rules for how they should be installed. In theory, one could write code to install a wheel in any programming language. Non-wheel distributions, however, are a different matter entirely. A .tar.gz source distribution often relies on running a setup.py file, which requires a Python interpreter.

In the ideal world, PyOxidizer doesn't care about how a package is built: just the files that comprise the installed package. So wheels are a more desirable distribution format. In fact, PyOxidizer has Rust code for extracting wheels and repackaging their contents: no Python necessary. This means PyOxidizer can do things like download wheels targeting non-native architectures and it *just works*.

As good as wheels are, they are universal in Python land. There are tons of packages that don't have wheel distributions and continue to offer the older .tar.gz distribution format.

We would like to see a concerted effort to push harder for the presence of wheels. For example, PyPI could encourage/nag package maintainers to upload wheels.
